As a result of mechanical interdependence of adjacent lung units, when inflation of some units lags behind that of others, large negative interstitial pressures can be generated around and within the lagging units. These negative pressures can be transmitted to the fluid-exchanging vessels (when there is airway closure), enhancing edema formation, especially in obstructive lung diseases such as asthma, bronchiolitis, and bronchopulmonary dysplasia (BPD), as well as in nonobstructive “stiff lung” disorders such as the respiratory distress syndrome (RDS).

## Increased Pulmonary Vascular Surface Area

The normal adult lung usually has approximately one-third of its microvascular bed perfused under resting conditions. Infants and young children have a greater percentage of their vascular bed distended with blood. Regardless of the absolute percentage, the lungs of all age groups can undergo significant recruitment and distention of the pulmonary vasculature. Although it had been suggested that various regions of the normal lung might have different permeability to solutes, most studies suggest that lung fluid movement simply increases in direct proportion to the increase in perfused pulmonary vascular surface area. Under normal conditions, the lung lymphatics can easily accommodate the threefold to fourfold increase in lung water and solute movement that is associated with full recruitment of the vasculature. However, when pulmonary vascular permeability is increased, similar amounts of recruitment can lead to marked increases in fluid movement as vessels with high permeability are recruited.[16,17]

## Increased Vascular Permeability in Fluid-Exchanging Vessels

Increased alveolar-capillary membrane permeability to solutes can occur by different routes. Classic modeling of the Pmv uses the concept of various sized “pores” through which various-sized solutes move under normal physiologic conditions. Thus, permeability could increase via an increase in the total number of pores, the diameter of the pores, or a combination of the two phenomena. For example, vasoactive agents could increase the size of the interendothelial junctions. Alternatively, or in addition, direct and extensive damage to the alveolar epithelium or endothelium occurring during overventilation lung injury[18,19] or stress-induced endothelial injury[20] will open up large nonphysiologic pathways for fluid and solute movement.

A variety of clinical conditions are believed to alter the permeability of the alveolar capillary membrane, presumably by damage to epithelial and endothelial cells. The cellular mechanisms for this injury can be divided into two major categories: direct and inflammatory-mediated lung injury.

Direct lung injury can occur when a toxic substance directly causes cell injury without a preceding inflammatory response. Direct lung injury is seen during the inhalation of a variety of noxious gases, including the oxides of sulfur and nitrogen, hydrocyanic acid, and aldehydes. Similarly, the inhalation of gastric acid can directly damage lung epithelium. These produce denaturation of proteins, cellular damage, and pulmonary edema.

Inflammation-mediated lung injury, as occurs in ALI and acute respiratory distress syndrome (ARDS), most frequently arises from leukocytes and their products. The unregulated release of leukocyte-derived toxic products occurs in response to direct injury or in response to various infective and inflammatory stimuli. These toxic products include reactive oxygen species (e.g., superoxide, hydrogen peroxide, hypochlorous acid, hydroxyl radical, peroxynitrite), proteolytic enzymes (e.g., elastase, collagenase, lysozyme), products of arachidonic acid (e.g., platelet-activating factor), and cationic proteins. Leukocytes have been implicated in animal models of ALI induced by the administration of endotoxin, hyperoxia, microembolization, and mechanical ventilation. Nonleukocyte-derived vasoactive mediators also can increase vascular permeability. Examples include histamine, prostaglandins, cytokines, proteases, and reactive oxygen intermediates.

Increased permeability of the microvasculature also occurs in a variety of disorders characterized by aberrant regulation of the immune system. These include hypersensitivity pneumonitis and pulmonary vasculitis, which can occur in various disorders such as acute pulmonary systemic lupus erythematosus.

When there is increased pulmonary vascular permeability, an increase in microvascular hydrostatic pressure[16] or pulmonary blood flow[17] produces a much greater outward flow of fluid. As such, the combination of increased permeability and high LA pressures represents an especially difficult clinical challenge.

## Clearance of Pulmonary Edema Fluid

Once the basic condition producing the edema is reversed, how quickly pulmonary edema resolves depends on whether the fluid is confined to the interstitium, from which it can be cleared in hours, or is also located in the alveolar space, from which it may take many hours or days to clear.

Interstitial fluid has two pathways for clearance. The lymphatics play the most important major role; however, a second site is the venular end of the microvascular bed where *Pmv* has decreased and the balance of Starling forces can favor reabsorption. Alveolar edema fluid, after being actively transported across the epithelium, is returned to the circulation either by direct entry into the Pmv across the thin side of alveolar capillary membrane or by the lymphatics after it has been translocated back to the interstitial space. Both of these potential pathways, however, require water and solutes to have first traversed the distal lung epithelium.

In both high-pressure and high-permeability pulmonary edema, there is a substantial amount of protein within the alveolar fluid that opposes protein osmotic reabsorption, and it has been shown that passive forces cannot explain the clearance of alveolar fluid from the intact lung.[21] Long-term studies have demonstrated that as edema fluid is reabsorbed, the protein concentration in the alveolar space actually increases to levels above those in the plasma. This suggests that an active transport of salt and water was involved in the clearance of airspace fluids. Numerous studies, as reviewed recently,[22] have demonstrated that nonprimate mammalian and human distal lung epithelium actively transports $Na^+$ with $Cl^-$ and water following (Fig. 36.2). Although most research, for reasons of feasibility only, have focused on the alveolar type II epithelium's ability to actively transport salt, it is known that both the alveolar type I epithelium and Clara cells play important roles in this active epithelial $Na^+$ transport.[22] Studies in adult patients[23,24] have indicated that active alveolar fluid clearance rates in the human are in the range of 25% per hour.

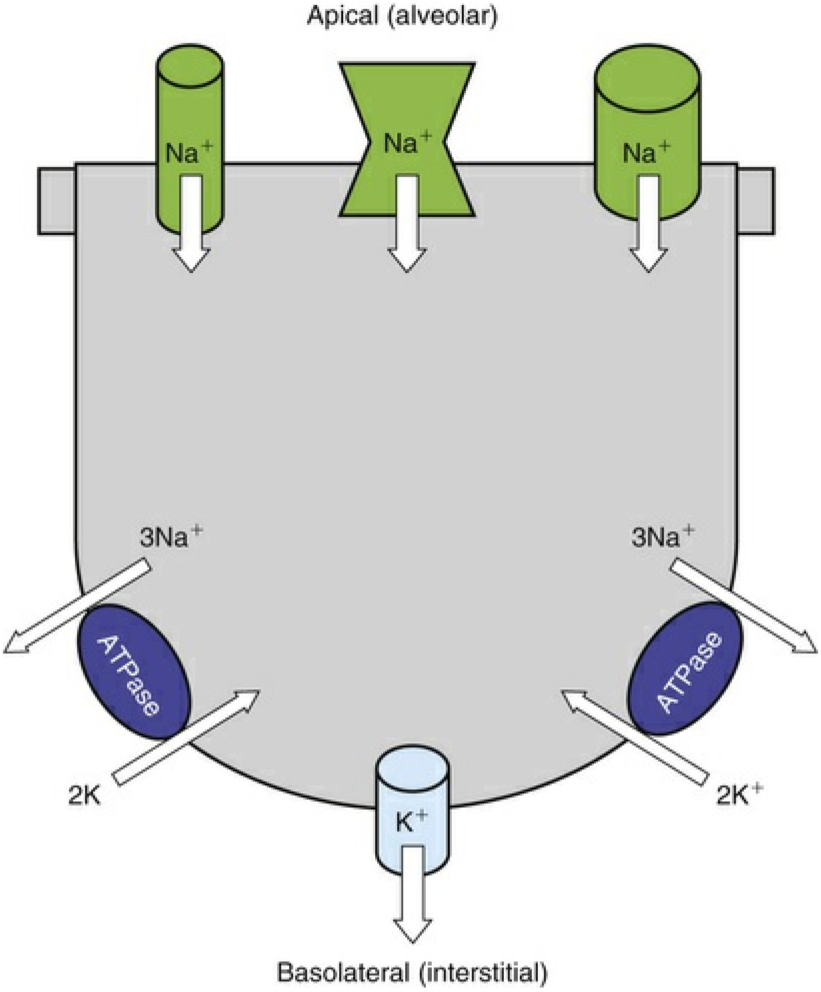

**FIG. 36.2** Model for Na$^+$ transport by the alveolar epithelium. The Na$^+$/K$^+$ ATPase located on the basolateral membrane is responsible for the creation of the marked intracellular/extracellular (10 : 150 mM) Na$^+$ concentration gradient. This chemical gradient along with the negative intracellular electrical potential arising from the permeability of the K$^+$ channels attracts Na$^+$ ions into the cell through Na$^+$-permeant ion channels located in the apical membrane to be extruded across the basolateral membrane. There are different types of Na$^+$ channels in the apical membrane, the most important of which is the amiloride sensitive epithelial Na$^+$ channel (ENaC). The activity of these Na$^+$-permeant ion channels represents the rate-limiting step in Na$^+$ transport. Chloride (Cl$^-$) follows both via the paracellular pathway past the tight junctions and through the cell via the Cl$^-$ channel encoded by the cystic fibrosis transmembrane conductance regulator (CFTR). Water follows in response to the osmotic gradient created by the active

ion transport. For more details, see reference 22.

Protein clearance from the alveolar spaces is significantly slower than salt and water, and in animals, it is in the range of 1% per hour.[21] The relative amount of protein cleared by metabolic degradation and macrophage ingestion versus active transport by the pulmonary epithelium is unknown, but active transport is involved in the clearance of at least some proteins from the airspaces of the lungs.[25] Protein clearance from the interstitial space is believed to occur primarily by lymphatic clearance, but direct penetration into the circulation either before or after metabolic degradation might also occur.

The presence of protein in the alveolar and interstitial spaces may attract inflammatory cells. In ALI syndromes, there is marked leakage of plasma protein into the alveolar space, and resultant activation of the coagulation cascade results in fibrin formation. The coagulum opposes the efficient reabsorption of fluid, and fibrin and fibrin degradation products are potent stimuli for fibrosis within the lung. Circulating monocytes and alveolar macrophages likely play a major role in the clearance of inflammatory edema protein from the lung's airspaces.

In summary, a wide variety of mechanisms and sites exist for protein and electrolyte clearance and fluid removal, including pulmonary and bronchial circulations, lymphatics, active transport of ions, macromolecular metabolism and degradation, and mononuclear cell activity.

## Pathophysiologic Consequences of Edema

The pathophysiologic consequences and clinical findings in pulmonary edema are best understood by reviewing the sequence of events that lead from interstitial to airspace edema. Edema accumulates within the lung in a step-wise fashion (Fig. 36.3). Distal lung units in different regions of the lung will be at different stages of fluid accumulation because of their regional differences in pressure, alveolar-capillary membrane integrity, and gravitationally dependent factors.

**FIG. 36.3** Schematic representation of the sequence of fluid accumulation during acute pulmonary edema. (A) Normal alveolar walls and no excess fluid in perivascular connective tissue spaces. (B) Initial fluid leak. Fluid flows to the interstitial space (at subatmospheric pressure) around the conducting vessels and airways. (C) Tissue space fills, alveolar edema increases, and fluid begins to overflow into the alveoli, notably at the corners where curvature is

pronounced. (D) Quantal filling. Individual alveoli reach a critical configuration at which existing inflation pressure can no longer maintain stability. Note that the fluid filled alveoli are smaller in size than their adjacent air-filled alveoli. The insert is a photomicrograph of a flash frozen lung with pulmonary edema that illustrates the above scheme of fluid filling. (From Staub NC, Nagano K, Pearce ML. Pulmonary edema in dogs, especially the sequence of fluid accumulation in lungs. *J Appl Physiol.* 1967;22:227-240.)

Increased pulmonary blood volumes, even without associated pulmonary edema, have been shown to cause a small decrease in lung compliance. Consistent with these findings, clinical studies have shown that infants with left to right congenital heart disease have low lung compliance that improves after correction of their shunt.[26]

In humans, the increase in airway resistance that occurs when there are small amounts of interstitial edema arises largely from a vagally mediated reflex.[27] Once interstitial edema worsens, the peribronchiolar cuffs of fluid would be expected to lead to increased closing volume and airway resistance, although this has been difficult to prove in morphometric studies of adult nonprimate lungs.[28] When small airways contribute a relatively greater proportion of the total airway resistance, as is the case in infants in contrast to adults, edema can lead to a greater increase in airway resistance. Small airway obstruction has been a presenting sign of a group of infants with ventricular septal defects and left-to-right shunts.[29] In addition, some children with interstitial edema as a result of LA obstruction (e.g., cor triatriatum) have also presented with a history of recurrent asthmatic attacks. To minimize the markedly increased work of moving their stiff lungs, a pattern of rapid, shallow breathing is used. The stimulation of vagal J receptors by the edema also contributes to the tachypnea and dyspnea so characteristic of early pulmonary edema.

For reasons previously outlined, the presence of edema increases airway resistance. As the airways narrow, closing volume increases and alveolar gas exchange is impaired because of the resultant low V/Q ratio. At this stage, hypocapnia results from the J receptor vagally mediated reflex hyperventilation independent of the presence of hypoxemia. As edema worsens and alveolar flooding occurs, there is further hypoxemia as the blood shunts past nonventilating alveoli. Respiratory acidosis may supervene if the patient is depressed by sedation or if exhaustion develops. The extent to which bronchial mucosal edema intensifies the increase in airway resistance when pulmonary edema is accompanied by elevated systemic venous pressure is not known. With alveolar flooding and disruption of the normal alveolar lining, resistance to airflow increases, dynamic and static compliance are reduced, and there is increasing inhomogeneity of airflow. Once the edema fluid floods into the airspaces, the proteins therein impair surfactant function.[30] One can account for most of the clinical findings (e.g., crackles and diffuse wheezing) based on interstitial, airway, and alveolar edema.

# Clinical Presentation

## Physical Examination

In a general way, small increases in lung fluid are too subtle to be detected by currently available clinical methods, and only when the extravascular fluid volume has increased considerably is the condition clinically obvious. The patient will be tachypneic not just when hypoxemia stimulates ventilation but also because of the stimulation of the J receptors. This latter point explains, at least in part, the continuing tachypnea even after correction of arterial hypoxemia by supplemental oxygen therapy. On auscultation, crackles occur when edema fluid is present in the terminal airways, and they are produced by the sudden opening of peripheral lung units (terminal bronchioli and alveolar ducts). When the fluid moves up to larger airways, rhonchi and wheezes are to be expected. The relative contribution of bronchial wall edema and bronchoconstriction to rhonchi and wheezes is not known. Chest wall retractions will be observed as the spontaneously breathing patient must generate more negative pleural pressures to overcome the markedly decreased total respiratory system compliance and mild increases in airway resistance. Grunting may be present in pulmonary edema and represents a useful maneuver to create a positive end expiratory pressure to prevent derecruitment of distal lung units.

## Pulmonary Function Tests

Initially, vascular engorgement may lead to an *increase* in the diffusing capacity (DLCO) by increasing the amount of perfused vasculature within the gas exchanging regions of the lung. As interstitial edema increases, there will be an increase in closing volume, a decrease in maximum expiratory flow, an increase in V/Q inhomogeneity, and a decrease in arterial $PO_2$. With alveolar flooding, there is further air trapping, increased vascular resistance, decreased lung volumes, decreased dynamic lung compliance, decreased DLCO, and progressive hypoxemia arising from the increased intrapulmonary right-to-left shunting and rising $PaCO_2$, the latter further decreasing alveolar $PO_2$. In patients with a patent foramen ovale, right-to-left shunting at the atrial level may occur as a result of the associated pulmonary hypertension and concomitant increase in right ventricular end diastolic and right atrial pressures.

## Imaging Studies

It has been shown that an infusion of 30 mL/kg of saline into healthy adult volunteers over 30 minutes increases extracellular fluid volume by 15% without altering the density of the lungs on computed tomography (CT) or the amount of Compton scattering; the only change on chest radiography and 1980 era CT studies was an increase in the size of the azygos vein.[31] To this author's knowledge, human studies such as these have not been repeated and modern imaging techniques would likely be more sensitive.

### The Chest Radiograph

Pulmonary edema can be detected in adult humans on a chest radiograph when extravascular lung water (EVLW) is increased by approximately 35%. Although most of the radiographic signs of pulmonary edema are nonspecific, improved radiographic techniques in conjunction with improved understanding of the pathophysiology of pulmonary edema have enhanced the usefulness of the chest roentgenogram in the diagnosis of pulmonary edema.

The Kerley lines represent interlobular sheets of abnormally thickened or widened connective tissue that are tangential to the x-ray beam (Fig. 36.4). These are more properly referred to as septal lines. Thickened septal lines may occur from a variety of processes, including fibrosis, pigment deposition, and pulmonary hemosiderosis. However, when they are transient, these lines are usually caused by edema. These septal lines of edema are more clearly visible in older children and adults with chronic edema than in infants, presumably because they are wider. Perivascular and peribronchial cuffing are also radiographic signs of interstitial edema fluid. For hydrostatic reasons, perivascular edema is greatest in the gravitationally dependent regions, and the normal tethering action of the lung is therefore less in this region. Increased resistance in the lower lobe vessels promotes the redistribution of blood to the upper lobes. This sign is, of course, of limited value in infants, because they are most likely to be in the supine position, have smaller gravitational induced differences because of their size, and normally have only slightly increased PA pressures relative to children and adults.

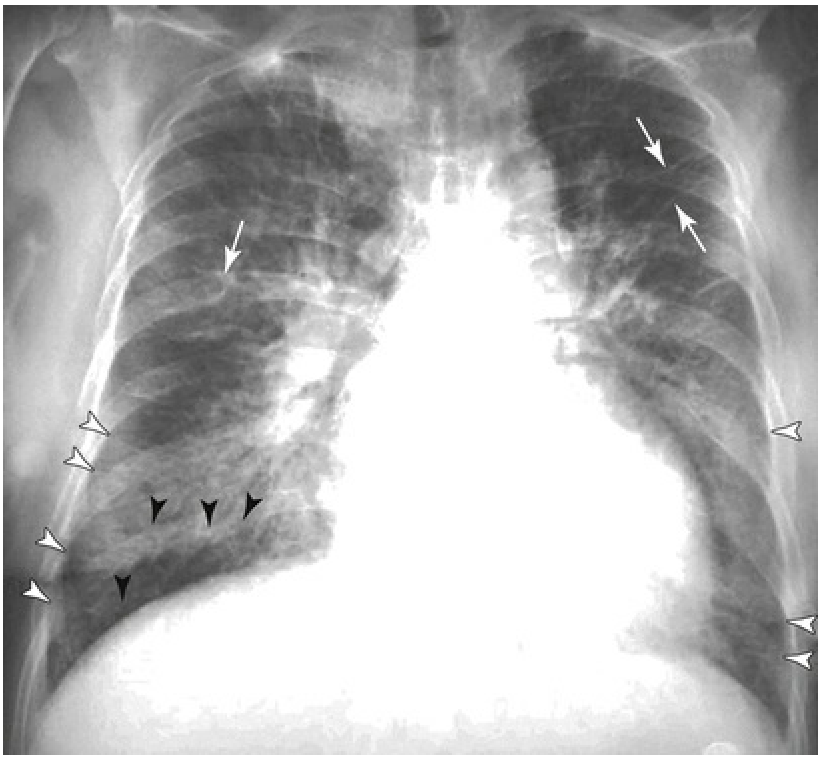

**FIG. 36.4** Kerley's A lines *(arrows)* occur in the upper lung zone and point towards the hilum and are directed toward, but do not extend to, the pleural surface. Kerley's B lines *(white arrowheads)* are usually in the lung base and are at right angles to, and in contact with, the pleural surface. Kerley's C lines *(black arrowheads)* are reticular opacities representing Kerley's B lines seen *en face.* (Reproduced from Koga T, Fujimoto K. Images in clinical medicine. Kerley's A, B, and C lines. *N Engl J Med*. 2009;360[15]:1539.)

More severe forms of pulmonary edema commonly produce a perihilar haze, presumably because the large perivascular and peribronchial collections of fluid are in this location. A reticular or latticelike pattern also may be present and is more common inferiorly in an upright individual. Once the magnitude of pulmonary edema is sufficiently severe to lead to persistent airway closure or alveolar flooding, it is very difficult to separate edema, atelectasis, and inflammation on chest radiographs. Air bronchograms indicate airless distal lung units and not the underlying cause.

Because pulmonary edema can lead to airway obstruction in children from both vagal reflex[27] and bronchial froth,[32] airway closure can occur and produce air trapping.[29] Thus, low diaphragms may be a useful sign of interstitial edema, provided there are no other reasons for airway obstruction. Although studies in children are limited, a summary of findings that allows separation of cardiogenic or hemodynamic edema, renal or overhydration edema, and injury or ARDS edema has been provided in adults.[33,34] There is an inverted base-to-apex redistribution of blood flow in patients with heart failure. The progressive recruitment of connective tissue spaces by edema fluid in both cardiac and renal disease gives rise to hilar blurring, peribronchial cuffing, and a hazy pattern of increasing lung density. In ARDS, there is more likely to be a patchy peripheral distribution of edema and a paucity of such findings as septal lines and peribronchial cuffing.

## Computed Tomography and Magnetic Resonance Imaging

Thin-section CT imaging of the thorax has provided new information regarding pulmonary edema (Fig. 36.5). For example, studies in ARDS have shown that the lung densities, presumably representing regional edema and microatelectasis, are very heterogeneous and shift with the position of the patient, with densities appearing in the most gravitationally dependent lung regions.[35–37] However, alterations in lung density have to be interpreted with caution. Increases in regional lung density can result from increases in EVLW (i.e., edema), a decrease in regional gas volume, or both.

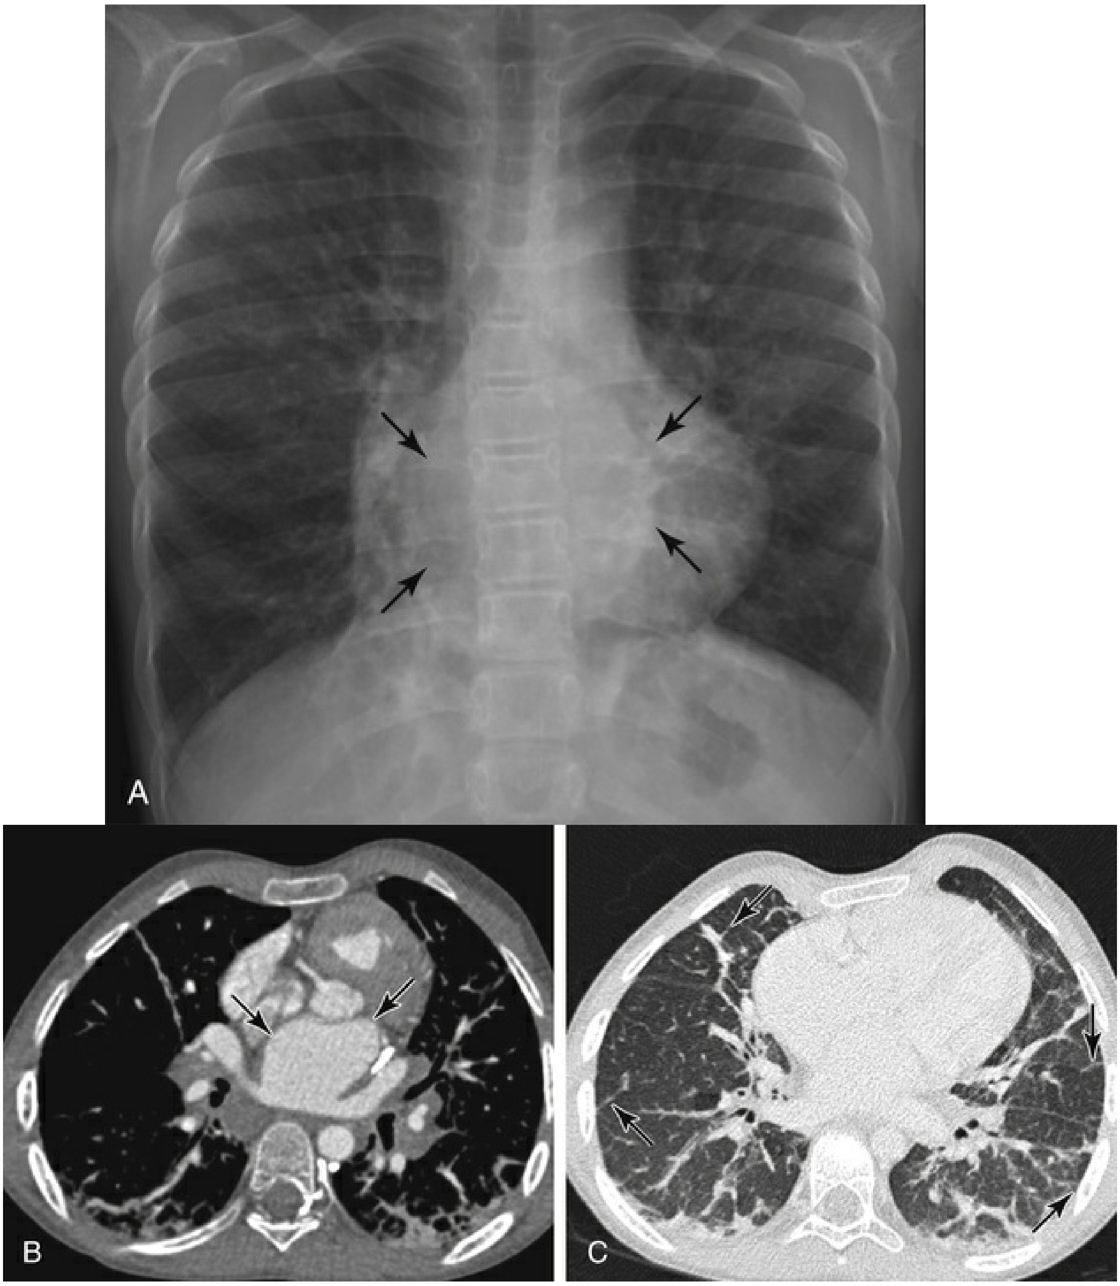

**FIG. 36.5** Images of a 7-year-old patient with Shone syndrome and long-standing mitral stenosis. (A) Frontal chest radiograph reveals mild cardiomegaly with an enlarged left atrium *(arrows).* There is vascular prominence of the upper lobes and features of the interstitial edema, including hyperinflation, perihilar prominence of vessels, and indistinct vascular margins. (B) CT (mediastinal windows) illustrates the enlarged left atrium *(arrows)* and pulmonary veins. (C) CT (lung windows) illustrates prominent vessels, areas of mosaic perfusion (darker and lighter regions) indicating small airway dysfunction and interlobular septal thickening *(arrows),* which are the CT equivalent

of Kerley B lines on plain chest radiographs. (Images courtesy of Dr. Beverley Newman, Stanford University.)

To date, magnetic resonance imaging (MRI) has had limited use in the management of patients with pulmonary edema. Its major advantage is that it does not require ionizing radiation. One major limitation is that despite obtaining excellent imaging of the larger pulmonary vessels, MRI provides relatively poor resolution of the lung's parenchyma. The safe transport to and the management of the patient within the MRI suite are also pragmatic limitations to this imaging modality. However, one center with a MRI within their critical care unit has used this approach to document that there is increased lung water content in premature babies with RDS.[38] Their findings are consistent with earlier studies of gravimetric measurement of lung water content in postmortem premature infants[39] and research studies on experimental RDS in nonhuman primates (see Neonatal Respiratory Distress Syndrome).[40]

## Distinguishing High-Pressure from Low-Pressure Pulmonary Edema

Direct measurements of Pmv would be useful in the differentiation of high-pressure from high-permeability edema. However, the use of pulmonary artery occlusion pressures to estimate Pmv has its limitations (see Vascular Forces), and patients with pulmonary edema often have both increased permeability and elevated pulmonary artery occlusion pressures.[14] Although B-type natriuretic peptide (BNP) has been found useful in identifying congestive heart failure (CHF), it does not reliably distinguish CHF-induced from ARDS-induced pulmonary edema.[41]

When patients with pulmonary edema have undergone endotracheal intubation, one can collect airway fluid that may reflect alveolar fluid. On this basis, investigators attempted to differentiate high-pressure from increased permeability pulmonary edema[42] by comparing the concentration of the protein in the airspace fluid with the simultaneously measured plasma protein concentration. Although this ratio was statistically significantly different between the two groups, there is such significant scatter that it is of little diagnostic utility for the individual patient. The reason for this variation and lack of clinical utility is now understood: the alveolar fluid's protein concentration not only depends on the leakiness of the alveolar-capillary membrane, but also on the efficiency and amount of time available for the epithelium to actively pump salt and water out of the airspace with the resultant concentration of the protein that remains in the distal lung unit (see Clearance of Pulmonary Edema Fluid).

Endothelial cell injury has been assessed by the ability of the pulmonary circulation to remove or metabolize a variety of substances; however, these tests are neither sufficiently sensitive nor specific. Similarly, although the clearance rate of inhaled and deposited small solutes (e.g., $^{99m}$technetium diethylenetriamine-pentaacetic acid [Tc-DTPA]) from the lungs provides an index of pulmonary epithelial integrity,[43] this approach is hampered by the inability to differentiate increased epithelial permeability from marked increases in regional lung volume.[44] Analysis of airspace fluid may be beneficial, as proteomic analysis may reveal qualitative changes in the expression of some proteins and might provide markers for lung injury.[45] Similarly, investigators have attempted to use plasma biomarkers to detect ALI.[46]

## Quantitation of Pulmonary Edema in Patients

Indicator dilution techniques have been used to measure EVLW content in humans. Traditional techniques have used a technique that depends on one tracer being confined to the vascular space and another tracer that diffuses into the perfused tissue. The difference in the sum of the two time concentration curves has been used to calculate the amount of EVLW. Measurements of EVLW are improved when results are normalized to lung volumes as predicted by height and gender rather than the previous approach of body weight, which is affected by obesity.[47] Useful information has been obtained using this approach. For example, EVLW correlates with mortality in critically ill adults (Fig. 36.6).[47,48] The major assumption, and limitation, of these techniques is that it can only measure that portion of the lung that is perfused; therefore, it may underestimate the total lung water or measurements may assess differing amounts of the lungs at different time points.[49]

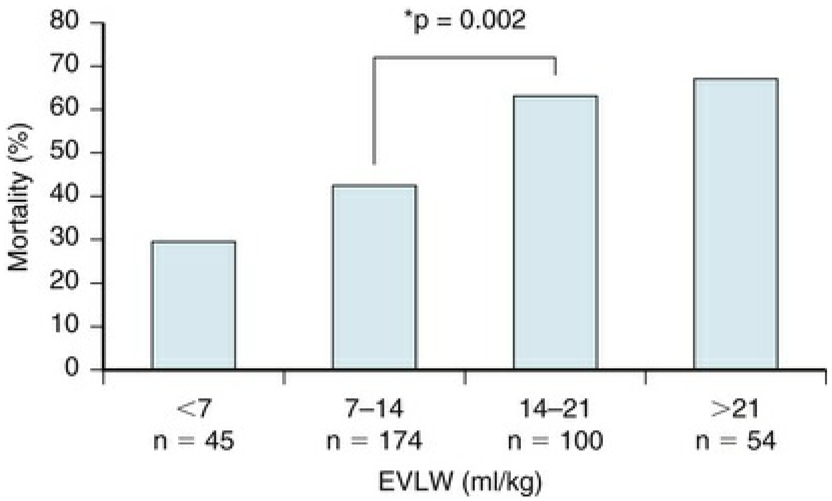

**FIG. 36.6** Mortality as a function of extravascular lung water (EVLW). Patients were classified into four groups according to their highest EVLW value. The asterisk indicates statistical significance to the next higher EVLW group (chi-squared). (Reproduced from Sakka SG, Klein M, Reinhart K, Meier-Hellmann A. Prognostic value of extravascular lung water in critically ill patients. *Chest*. 2002;122[6]:2080-2086.)

# Clinical Disorders Causing Pulmonary Edema

## High-Pressure Pulmonary Edema

This diagnostic label refers to conditions where there is a demonstrable increase in the forces promoting fluid movement out of the microvasculature. By far the most common cause is left-sided heart disease, which results in marked elevations of pulmonary venous and hence microvasculature hydrostatic pressure.

Obstructive lesions such as cor triatriatum, mitral stenosis, congenital obstruction of pulmonary venous drainage, and pulmonary venoocclusive disease directly cause pulmonary venous hypertension. In contrast, other obstructive lesions such as coarctation of the aorta and severe aortic stenosis only cause pulmonary edema once left ventricular failure has occurred.

Myocardial failure with subsequent pulmonary venous hypertension may arise from either congenital or acquired heart disease. Examples of the former include hypoplastic left heart syndrome, and the latter includes intrinsic myocardial disease (e.g., cardiac glycogen storage diseases, endocardial fibroelastosis, viral and rheumatic myocarditis) and myocardial ischemia (e.g., anomalous left coronary artery or Kawasaki disease).

Markedly increased pulmonary blood flow occurs in patients with congenital arteriovenous fistulas or congenital heart defects that promote left-to-right shunting of blood (e.g., ventricular septal defect, patent ductus arteriosus). This leads to pulmonary vascular engorgement, especially in the case of anatomic left-to-right shunting. In either case, there is a marked increase in left ventricular output. When the burden on the left ventricle becomes too great and left-sided heart failure supervenes, pulmonary microvascular pressures are increased by both high flow and increased LA pressures.

Significant increases in blood volume can result in pulmonary vascular engorgement and edema. Fluid retention rapidly occurs in acute renal disease as a result of the expanded extracellular fluid volume. Nephrosis and chronic renal disease also may predispose an individual to pulmonary edema by the associated hypoproteinemia. Perhaps the most common cause of increased pulmonary blood volume is the overzealous administration of fluids. This will intensify the development of pulmonary edema by raising hydrostatic pressures and diluting plasma proteins. Finally, to what extent the inappropriate secretion of antidiuretic hormone, which occurs in disorders such as pneumonia, asthma, and BPD, complicates and intensifies the development of pulmonary edema in these diseases is incompletely understood.

## Airway Obstruction

Severe obstruction of the extrathoracic airways predisposes the patient to pulmonary edema (see Interstitial Forces). For example, croup and epiglottitis are associated with pulmonary edema.[50,51]

Diffuse small airway obstruction, as occurs in status asthmaticus, also promotes the development of pulmonary edema as a result of a lag in the expansion of the lung in spite of the development of very negative intrathoracic pressures.[52] Although airway inflammation is recognized as an important part of the pathogenesis of asthma, it is not clear to what extent edema of the airways, per se, plays in the airway obstruction. Certainly, any inflammation-induced increase in permeability would dramatically increase the amount of fluid moving across the vascular bed in response to a more negative interstitial pressure. Clinically, significant short-term improvements in gas exchange may be seen in some patients with asthma and bronchiolitis with the use of diuretics. Because these diuretics also change vascular compliance and pressures, the exact reason for the beneficial response is uncertain. Nevertheless, our improved understanding of how airway obstruction can promote the development of pulmonary edema led to the present therapeutic strategy of giving only maintenance, or less than maintenance fluids, to patients after they have had their deficits replaced. In the more distant past, it had been customary to advocate increased fluid intake for patients with asthma and bronchiolitis in the false hope that the increased fluid would loosen secretions and facilitate their expectoration; this has never been established, but it is certain that the increased amounts of fluid will promote the development of pulmonary edema.

Cardiac failure and pulmonary edema are also rarely seen in obstructive sleep apnea; in children, this condition is most frequently associated with hypertrophied tonsils and adenoids.[53,54] At the bedside, one can see severe intercostal retractions during inspiration. Indeed, this inspiratory pattern is similar to a Müller maneuver (i.e., a strong inspiration against a closed glottis or obstructed upper airway). The negative pressures would, in addition to promoting edema, also surround and restrain the left ventricle and create an increased afterload to the left ventricle (left ventricular afterload is equal to the mean aortic pressure minus the pleural pressure).

## Reexpansion Pulmonary Edema

Reexpansion pulmonary edema is seen in some patients who have rapid lung reexpansion after drainage of a large pneumothorax or pleural effusion. Rarely, it causes systemic hypovolemia and shock, as large volumes of fluid move from the vascular space to airspaces of the rapidly reinflated lung.

The reported incidence of reexpansion pulmonary edema varies considerably, and it has been speculated that the different incidence rates result from various factors. These include the duration of the atelectasis, characteristics of the collapsed lung, and the rate of evacuation of the pleural air or fluid. For example, in many of the case reports, the lung collapse had been present for some time before reexpansion. A prospective study revealed that 20% of adult patients treated with closed thoracostomy drainage for a spontaneous pneumothorax developed classic reexpansion pulmonary edema.[55] In contrast, another report found that the evacuation of pleural fluid was rarely associated with reexpansion pulmonary edema.[56] Regardless of the true incidence, it is irrefutable that this phenomenon does occur. Thus, caution must be exercised when draining large collections of fluid from the pleural space when there is associated collapse of a lobe or lung.

One of the mechanisms responsible for the syndrome is the sudden marked lowering of the interstitial fluid pressure. In addition, experimental studies of reexpansion pulmonary edema in rabbits[57] provide evidence that there is increased vascular permeability to protein. Although the mechanism for injury of the alveolar-capillary membrane is not known, there are at least two possibilities. The first is that there is increased and excessive stretch or tension of the alveolar septal walls during reexpansion of lungs that have been collapsed for several days. Stress-related pulmonary endothelial injury[20] has been described in other experimental conditions, and overexpansion of lungs during positive-pressure ventilation is associated with increases in alveolar-capillary permeability.[18,19] Other mechanisms, such as reperfusion lung injury from reactive oxygen intermediates, also may play a role in the increased alveolar-capillary membrane permeability. Indeed, it has been shown that collapsed lung tissue has decreased mitochondrial superoxide dismutase (SOD) and cytochrome oxidase[58]; these changes could enhance oxygen free radical production.

## Neonatal Respiratory Distress Syndrome

Studies in humans[38,39] and primates[40] prove that neonatal RDS (nRDS) in premature infants is associated with widespread airspace edema and that the well-described reduction in FRC results more from the excess fluid than from atelectasis.[40]

A number of factors contribute to airspace fluid in patients with nRDS. First, there is the fluid that had been secreted into the developing fetal lungs' airspaces during normal fetal lung development. This fluid must be cleared at birth so that effective gas exchange can occur, and clearance of airspace fluid results from active transepithelial $Na^+$ transport (see Fig. 36.2). Impaired clearance of this fetal lung liquid arising from inadequate epithelial sodium transport[59,60] combined with an immature surfactant system,[61] results in nRDS.[62] Second, pulmonary edema fluid is generated during the course of nRDS by several mechanisms. These include the high pulmonary vascular pressures and blood flow, especially if there is a patent ductus arteriosus; low interstitial pressures, in part the result of high alveolar surface tension; low plasma protein concentration (and hence low plasma osmotic pressure)[63]; increased epithelial permeability[43]; lung endothelial injury from inflammation and, as a result of therapy, high airway pressures and high inspired oxygen concentrations.

## Neurogenic Pulmonary Edema

Any acute cerebral insult, and rarely cervical spinal cord injury, can lead to neurogenic pulmonary edema (NPE).[64,65] Most frequently, it is seen with head trauma, subarachnoid hemorrhage, brain tumors, status epilepticus, and meningitis. The mechanisms responsible for pulmonary edema following lesions of the brain are not fully understood but appear to result from a combination of hemodynamic and permeability-altering factors. The hemodynamic response arises from a sympathetic storm that causes intense brief vasoconstriction from mediators such as norepinephrine, neuropeptide Y, and endothelin. Vascular permeability is also increased. This might occur by two mechanisms: pressure induced damage to the vascular bed or from the release of factors, such as tumor necrosis factor (TNF)-$\alpha$, interleukin-1$\beta$, and interleukin-6, from astrocytes and microglial cells, which may gain entry into the systemic circulation. These along with inflammatory processes arising from the sympathetic storm may induce a systemic inflammatory response.

The clinical signs of NPE are those of acute pulmonary edema, without evidence of left ventricular failure. There is no specific biologic marker for NPE, and it may develop acutely over minutes to hours or may be delayed. Evaluation of edema fluid suggests that patients may either have predominately high pressure or high permeability pulmonary edema.[66] In the treatment of NPE, it is important to remember that positive ventilatory pressures, especially positive end-expiratory pressure (PEEP), should be administered cautiously because they can interfere with cerebral venous return, thus promoting further cerebral edema. Depending on the severity of the primary result, NPE may resolve within the first 2–3 days and overall outcome relates to the neurologic outcome.

## Acute Lung Injury and the Acute Respiratory Distress Syndrome

ALI and its most severe form, ARDS, frequently occur in critically ill patients. Regardless of the inciting event, the clinical and pathologic manifestations of ARDS are similar, indicating a final common pathway ultimately leading to severe endothelial and epithelial inflammatory injury. This causes a compromise of barrier and transport functions, which leads to high permeability pulmonary edema that is often compounded by increases in microvascular pressure from concomitant pulmonary hypertension and pulmonary venoconstriction.

An initiating event, such as sepsis, shock, head injury, or trauma triggers a systemic inflammatory response that promotes sequestration of polymorphonuclear leukocytes (PMN) within the lung. Histologically, ARDS is characterized by large numbers of PMN in the vascular, interstitial, and alveolar space in association with endothelial and epithelial injury. This, combined with the potential of PMN to induce tissue injury in diverse experimental systems, has led to the widely held concept that these potent phagocytes are central to the pathogenesis of ARDS, a notion supported by numerous human and animal studies. The clinical presentation, pathogenic mechanisms, and approaches to therapy are discussed in detail in Chapter 38.

## High Altitude Pulmonary Edema

High-altitude pulmonary edema (HAPE) can occur when climbers are exercising intensively in hypoxic environments as they ascend to high altitudes. What are the relative contributions of exercise and hypoxia? Although pulmonary edema can occur during marathons conducted near sea level[67] or in elite swimmers,[68] it is extraordinarily rare for normoxic exercise to be associated with pulmonary edema. Similarly, moderate hypoxia by itself is not sufficient for the development of edema. Athough approximately one-third of nonexercising children who rapidly ascend to modest elevations (from 568 to 3450 m) develop acute mountain sickness (AMS), clinically obvious cerebral or pulmonary edema do not seem to occur.[69] Studies have shown that these symptoms of AMS can be prevented by the administration of acetazolamide, but not the herbal supplement ginkgo biloba, just before and during ascent.[70] Although exposure to even more modest hypoxia (equivalent to 2438 m altitude) is associated with small decreases in arterial saturation, it is not associated with AMS.[71]

Clinically important and severe HAPE may affect some sea-level dwellers soon after arriving at a high altitude. Arterial blood gas analyses suggest that there may be subclinical HAPE, or diffusion defect, even in asymptomatic climbers ascending Mt. Everest.[72] HAPE also may occur in some highlanders who return home after a brief stay at sea level.

Much of our initial understanding of HAPE came from observations of Indian soldiers transported to high altitudes during the Indo-China war of the past century.[73] Subsequent work has shown that the incidence of HAPE and AMS is increased when the rate of ascent is rapid and subjects have little opportunity for acclimatization, whereas gender or previous altitude exposure have no effect.[74] Relevant to the previous discussion regarding pulmonary vascular recruitment, the incidence of HAPE is increased in children and young adults[75] and in subjects with only one pulmonary artery.[76] Fatigue, dyspnea, cough, and sleep disturbances are common and may progress rapidly to severe tachypnea, shock, and death unless rapid descent to a lower altitude or administration of oxygen occurs.

The mechanisms leading to HAPE are still incompletely understood. Nonprimate animal studies show that although hypoxia increases PA pressures, it does not by itself increase vascular permeability to solutes.[15] However, the best available evidence suggests that HAPE is initiated by an excessive increase in Pmv. The cause of the Pmv is unknown, although the two favored hypotheses are an unequal pulmonary vasoconstriction with resultant overperfusion of remaining lung microvessels or an abnormal vasoconstriction of the pulmonary venules. Prospective studies suggest that first there is a noninflammatory leakage of fluid across the alveolar-capillary membrane followed by a secondary inflammatory reaction[77] as the disease progresses.[78] Some researchers have assumed that in addition to a constitutional predisposition of some individuals to pulmonary hypertension with hypoxia, nonuniform increases in precapillary resistance are responsible for the very high pressures seen in at least some pulmonary capillaries. The observations that prophylactic administration of the calcium channel blocker nifedipine can diminish the incidence of HAPE[79] and that inhalation of nitric oxide (NO) decreases PA pressures and improves oxygenation[80,81] in such patients support the speculation that HAPE is due in part to an inappropriate pulmonary vasoconstrictive response. The observation that salmeterol diminishes the frequency of HAPE[82] is intriguing; potential mechanisms include its effect on vascular resistance and the augmentation of lung epithelial $Na^+$ transport.

## Inhalation of Toxic Agents

Toxic lung injury can be induced by a wide variety of agents,[83] but only three examples are discussed here. The most common agent is smoke from fires, the toxicity of which will vary with the nature of the combustible product (e.g., plastics vs. wood). In victims of fires, the auscultatory evidence of pulmonary edema resulting from inhalation of smoke with damage to the distal lung unit, including the alveolar capillary membrane, is manifest within 24 hours and usually precedes roentgenographic changes.[84]

Chlorine gas inhalation is an example of a toxic gas that can cause severe lung injury. It is most frequently seen in industrial accidents but can occur following exposure to fumes from liquid chlorine used in swimming pools. Pulmonary edema is frequently seen; however, if the patient survives, there are no long-term sequelae.[85]

The inhalation of phosgene gas may occur following industrial accidents or as a gas generated during fires involving plastics or other chemicals and solvents containing chlorine. Although symptoms may be mild at first, with apparent initial recovery, delayed onset noncardiogenic pulmonary edema may ensure. Accordingly, patients should be admitted to hospital for at least one day for observation.[86]

## Intravenous Agents

Infusion of any compound that can act as a microembolic agent can result in high-permeability pulmonary edema as demonstrated in animal models of lung injury[17] and humans who have accidentally suffered from air microembolism.[87]

## Narcotic-Induced and Medication-Induced Pulmonary Edema

Heroin and other narcotics also have been associated with pulmonary edema.[88,89] Pulmonary capillary Pw has been elevated in some patients but has been normal in others. Whether hypoxia and acidosis or NPE, as the result of cerebral edema, plays a role is not known. Clinical and roentgenographic signs of pulmonary edema have occurred following the intravenous administration of paraldehyde[90]; although a direct toxic action on the pulmonary vascular bed has been proposed, the cause remains obscure.

Salicylates also have been associated with the development of pulmonary edema in adults[91] and children.[92] Experimental studies in sheep suggest that salicylate pulmonary edema is not due to increased vascular pressure but rather to increased vascular permeability.[93] Insofar as these studies can be applied to the human, the researchers suggest that acetylsalicylic acid can cause pulmonary edema in doses considered therapeutic for some diseases. Although the mechanisms responsible for the altered vascular permeability remain unknown, at least two effects of salicylates could affect vascular integrity: alterations in platelet function and inhibition of prostaglandin synthesis.

## Therapy

It is not only biologically reasonable to maintain the postnatal airspace air-filled, and not fluid-filled; there is a substantial body of research that suggests that reduction or attenuation of pulmonary edema improves patient outcome. Decreasing PA Pws[94] or avoiding positive fluid balances[95] are both associated with improved survival. EVLW correlates with mortality in adults (see Fig. 36.6).[47,48] Similarly, a randomized study has shown that conservative fluid management improves lung function and shortens the duration of mechanical ventilation in ALI.[96] Indirect assessments of the distal lung epithelium's ability to actively transport $Na^+$, with $Cl^-$ and water following, from the airspace has been shown to correlate with survival and clinical outcome in both high-pressure and high-permeability pulmonary edema (Fig. 36.7).[24,97]

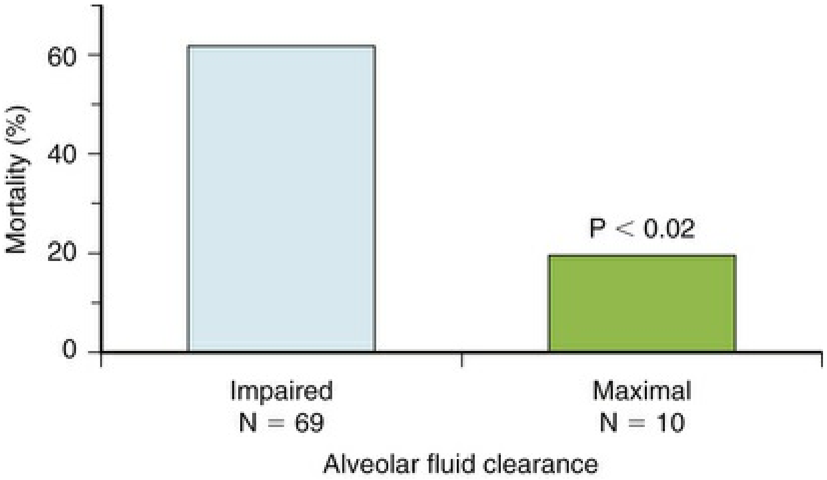

**FIG. 36.7** Plot of hospital mortality of two groups of patients with acute lung injury or the acute respiratory

distress syndrome: those with maximal alveolar fluid clearance (≥14% per hour) and those with impaired or submaximal alveolar fluid clearance (<14% per hour). Columns represent percent of hospital mortality in each group. Hospital mortality of patients with maximal alveolar fluid clearance was significantly less ($P < .02$). $N$ = number of patients. (Reproduced from Ware LB, Matthay MA. Alveolar fluid clearance is impaired in the majority of patients with acute lung injury and the acute respiratory distress syndrome. *Am J Respir Crit Care Med*. 2001;163:1376-1383.)

Therapy should be guided by the pathophysiologic consequences of the edema and the best method to decrease further movement of fluid into, and promote liquid clearance from, the airspace.

## Reversing the Hypoxemia

The first step is to reverse the hypoxemia. If pulmonary edema is mild and predominately interstitial in nature, then increasing the $FiO_2$ will treat the low V/Q ratios ($0 < V/Q < 1$) arising from airway dysfunction. However, most patients in acute pulmonary edema have significant airspace pulmonary edema, which results in shunt ($V/Q = 0$), and requires an increase in transpulmonary pressures as the therapeutic approach. Positive airway pressures in general, and PEEP, in particular, are beneficial for several reasons: (1) the recruitment (opening) of fluid-filled airspaces[35,36] so that they become partially filled with air and can then participate in gas exchange, (2) a reduction in the fluid filtration within the lung by impeding systemic venous return and therefore decreasing pulmonary vascular volume and pressure, and (3) the prevention of airway collapse, thus enhancing gas exchange. It is important to note that studies have shown that PEEP does not directly decrease lung water content[98] or lung lymph flow.[99]

An increase in transpulmonary pressures may be achieved using both noninvasive and invasive approaches. Although out of favor in the more distant past, it is now known that noninvasive ventilation can be effective in cardiogenic pulmonary edema.[100,101] Similarly, CT imaging has proven that when patients with ALI are placed in the prone position, there is recruitment of edematous lung units.[37] However, most frequently, intubation and assisted ventilation are required both for efficacy and to minimize potential side effects such as overdistention of the stomach and potential aspiration. Mechanical ventilation also reduces the oxygen consumption by reducing the work of breathing.

## Reduce the Rate of Fluid Filtration

The second step is to reduce the rate of fluid filtration into the lung. Treating the disorder creating the pulmonary edema, for example CHF, is self-evident. Several therapeutic approaches are useful in treating the CHF-induced elevation of pulmonary microvascular pressures. They include measures that (1) improve cardiac contractility and allow the heart to achieve an increased stroke volume at a lower filling pressure (e.g., use of oxygen, digoxin, dopamine, or dobutamine), (2) reduce preload, including the sitting position and positive-pressure ventilation, (3) reduce both preload and afterload by relieving anxiety (e.g., use of morphine), (4) decrease plasma volumes with concomitant reduction of pulmonary microvascular and LA pressures (e.g., administration of diuretics), (5) decrease systemic or pulmonary vascular pressures, or both, using vasodilators such as prostacyclin, nitroprusside, or inhaled nitric oxide, and (6) reduce excessive salt and water intake.

Small changes in lung microvascular pressures can have profound effects on lung water accumulation[16] and leakage of fluid from the microvascular bed (Fig. 36.8) when there is increased permeability of the alveolar-capillary membrane. Similarly, when there is increased permeability of the alveolar-capillary membrane, an increase in cardiac output, with minor changes in LA pressures, has a marked effect on lung lymph flow.[17] In humans who have undergone lung transplantation, echocardiographic evidence of diastolic dysfunction increases the risk of primary graft dysfunction, a condition characterized by increased alveolar capillary membrane permeability.[102]

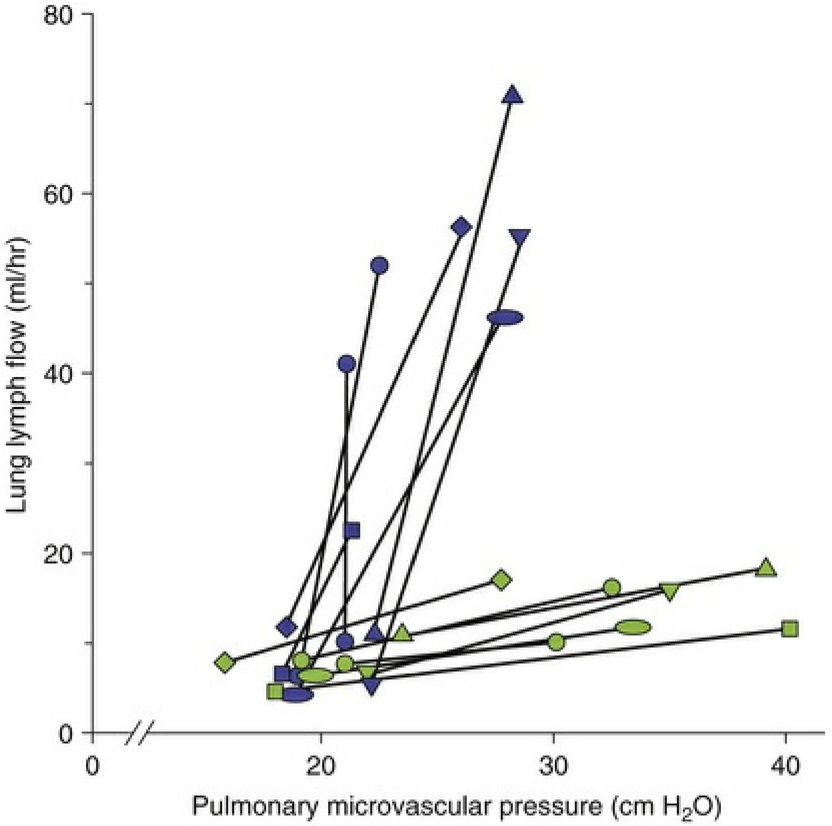

**FIG. 36.8** Relation of lung lymph flow to pulmonary microvascular pressures during hemodynamic edema *(green symbols)* and during permeability edema produced by infusion of *Pseudomonas (blue symbols).* For a given reduction in vascular pressures, there is a much greater reduction in lung lymph flow in permeability edema than in hydrostatic edema. (From Brigham KL, Wolverton WC, Blake LH, Staub NC. Increased sheep lung vascular permeability caused by *Pseudomonas bacteremia. J Clin Invest*. 1974;54:792.)

A reduction in the rate of fluid leakage from the vasculature can also be achieved using other strategies based on the Starling equation (see Factors Responsible for Fluid Movement). For patients suffering from ARDS and its associated high permeability pulmonary edema, our goal is to return the permeability of the alveolar-capillary membrane back to normal levels. Regrettably, despite decades of research, there is no proven way to modulate alveolar-capillary membrane permeability, although low-dose corticosteroids[103] or activated protein C in the subset of ARDS patients with sepsis[104] may be beneficial to some degree in altering the course of the overall disease. A randomized double-blind clinical trial that excluded patients with sepsis showed that the administration of protein C did not improve clinical outcomes in ALI.[105]

Starling's equation indicates that altering intravascular osmotic pressure would lessen the flow of fluid out of the microvasculature. However, an increase in colloid osmotic pressure resulting from an infusion of colloid also would augment microvascular pressure, as vascular volume is increased secondary to the movement of water from the systemic tissues to the vascular compartment and may undermine this effort. Indeed, studies in animals with high permeability pulmonary edema have shown that increasing colloid osmotic pressure had no effect on lung water content.[16]

Lowering systemic vascular pressures by use of diuretics and drugs that reduce vascular resistance or afterload are both advantageous for reasons previously described. However, diuretics such as furosemide are beneficial in pulmonary edema because of their ability to increase systemic venous capacitance and not because of the induced diuresis. Evidence for this statement includes the improvement in the patient's status, which is usually seen a few minutes after administering the diuretic before the diuresis. Similarly, furosemide can be beneficial in anuric patients suffering from pulmonary edema. It should be noted that the lung represents only 1% of the total body weight, so even a 1 L diuresis would only remove 10 mL from the lungs, with the remaining fluid coming from the remainder of the body. This 10 mL is trivial compared with the liters of fluid present in the airspaces of adult patients with florid alveolar edema (see Anatomic Considerations).

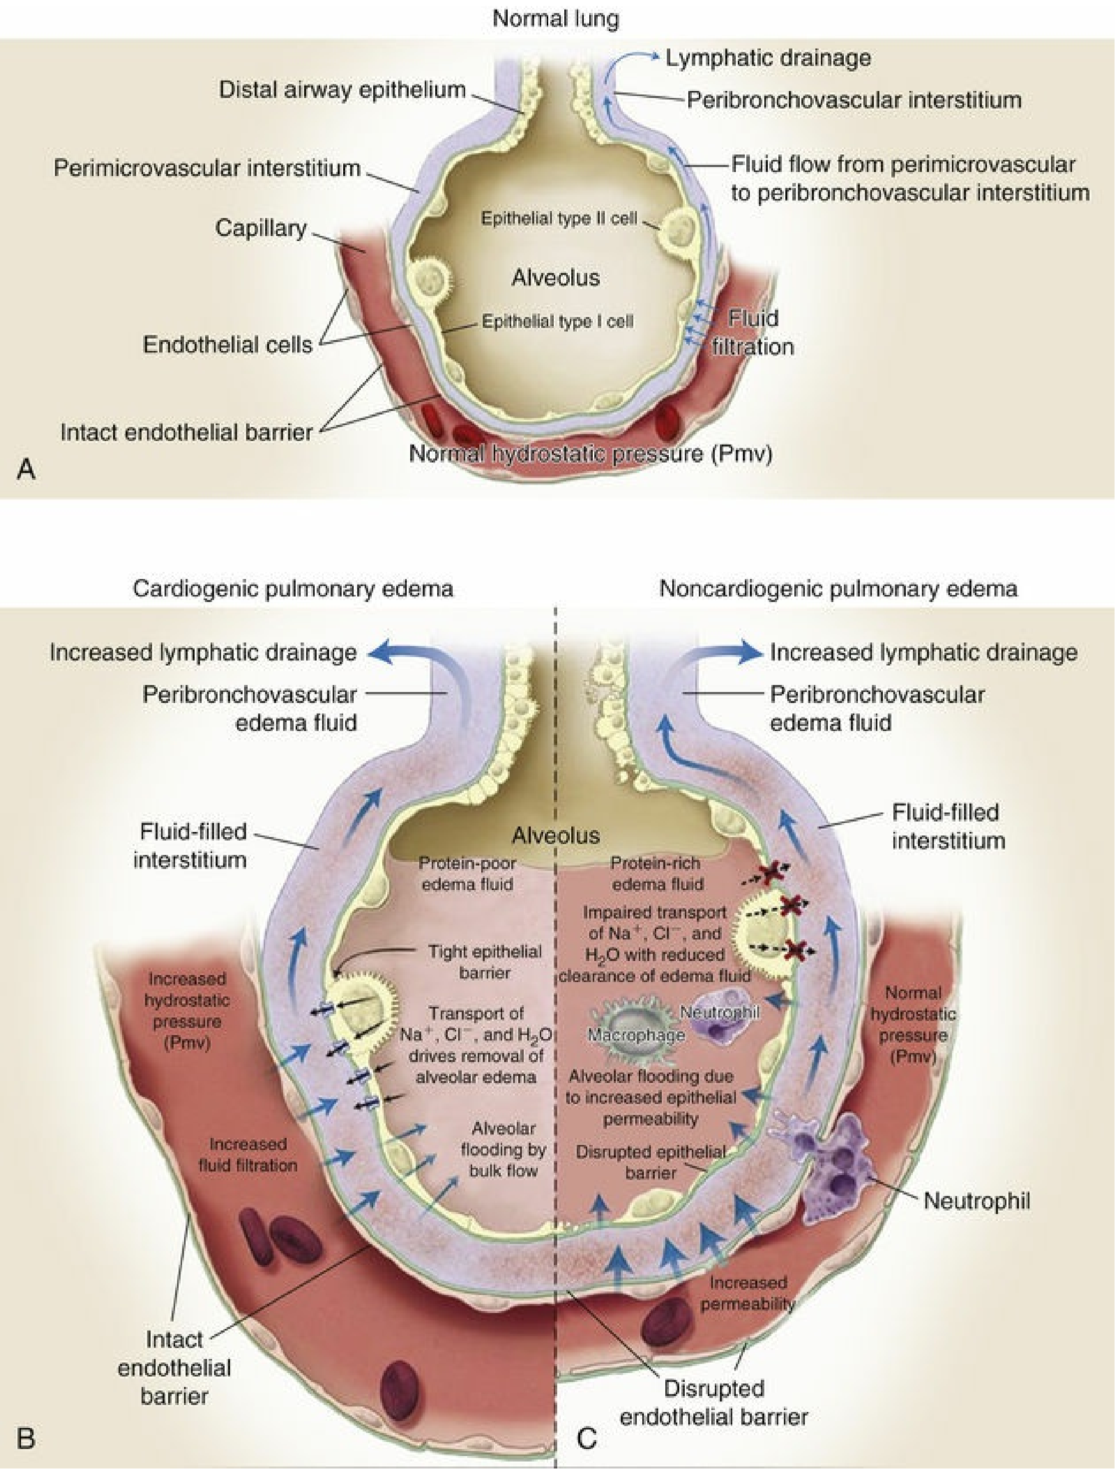
## Minimize Treatment-Related Lung Damage

It is important to prevent or minimize treatment-related damage to the lung. This can occur through the use of very high concentrations of oxygen or the suboptimal use of mechanical ventilation with resultant distention of the lung and damage to the lung's epithelium and endothelium,[18,19] thereby increasing the permeability of the alveolar-capillary membrane to water and solutes. Attention to treatment of the underlying condition combined with excellent supportive care using “lung-protective” ventilatory strategies to minimize treatment-related lung damage have contributed to improved clinical outcomes.[106] This subject is discussed in greater detail in Chapters 34, 37, and 38.

## Augment the Rate of Clearance of Airspace Fluid

The fourth step is to augment the rate of clearance of the airspace fluid. It has now been demonstrated that intact active fluid absorption from the airspaces correlates with improved survival and various important clinical parameters such as the length of assisted ventilation and oxygen requirements, regardless of whether the patients suffer from acute CHF-induced or ARDS-induced pulmonary edema (see Fig. 36.7).[24,97] Only 75% of patients with CHF-induced pulmonary edema have demonstrable alveolar fluid clearance, with approximately 40% being capable of achieving maximal clearance rates.[24] The situation is even more grave for patients with ALI and ARDS, because only 13% of these patients can achieve maximal rates of active airspace fluid clearance.[97] Active clearance of airspace fluid is impaired more frequently in men and when there is associated sepsis.[97]

Exogenous catecholamines augment fluid clearance from the airspaces in animals,[107] and a single center randomized controlled study showed that 7 days of intravenous salbutamol therapy is associated with a decrease in EVLW and ventilator pressures.[108] Consistent with these findings, aerosolized β agonists can decrease EVLW and improve clinical parameters in patients undergoing elective lung resections[109] and prevent HAPE in susceptible individuals.[82] However, studies in humans have not shown any correlation between the levels of circulating catecholamines and the rates of fluid clearance,[24,97] and a multicenter trial did not show a beneficial effect of aerosolized albuterol in ALI.[110] The lack of response in the multicenter study may have indicated the inadequate delivery of the aerosolized salbutamol to the airspace, that the epithelium is unresponsive, or that more efficacious strategies may be required to augment airspace fluid clearance. A clinical trial using an intravenous infusion of salbutamol was discontinued when it became apparent that it did not improve patient outcomes and was associated with an increase in mortality.[111] These clinical trials indicate that salbutamol should only be used to treat airway obstruction and not to increase the clearance of fluid from the alveolar spaces. New approaches are needed so that pulmonary edema fluid clearance can be increased without adverse side effects. Perhaps this may be developed from work showing that pulmonary edema fluid itself can modulate $Na^+$ and fluid transport by distal lung epithelium[112] or other studies where either mesenchymal stem cells (MSCs) or media conditioned by MSCs can restore effective Na+ and water transport by injured human lung lobes.[113] Fig. 36.9 provides a schematic overview of the distal lung unit during health and during high-pressure and high-permeability pulmonary edema.



Normal lung
Lymphatic drainage
Distal airway epithelium
Peribronchovascular interstitium
Perimicrovascular interstitium
Fluid flow from perimicrovascular to peribronchovascular interstitium
Epithelial type II cell
Capillary

C

**FIG. 36.9** (A) In the normal lung, fluid moves continuously outward from the vascular to the interstitial space according to the net difference between hydrostatic and protein osmotic pressures and to the permeability of the capillary membrane. (B) When transvascular hydrostatic pressure increases in the microcirculation, the rate of fluid filtration rises. Since the permeability of the capillary endothelium remains normal, the filtered edema fluid leaving the circulation has a low protein content. The removal of edema fluid from the air spaces of the lung depends on active transport of $Na^+$ and $Cl^-$, with water following across the alveolar epithelial barrier. (C) High-permeability pulmonary edema occurs when the permeability of the microvascular membrane increases because of direct or indirect lung injury, such as the acute respiratory distress syndrome, resulting in a marked increase in the amount of fluid and protein leaving the vascular space. The pulmonary edema fluid has a high protein content because the more permeable microvascular membrane has a reduced capacity to restrict the outward movement of larger molecules such as plasma proteins. In edema due to acute lung injury, alveolar epithelial injury commonly causes a decrease in the capacity for the removal of alveolar fluid, delaying the resolution of pulmonary edema. # Respiratory Complications of Intensive Care

*Hammad A. Ganatra MD, Brian Michael Varisco MD*

## History of Pediatric Intensive Care

The first pediatric intensive care unit (PICU) was established in 1955 at Children's Hospital of Göteborg in Sweden, followed by the emergence of PICUs in the United States in the late 1950s and early 1960s. These units originated to meet the medical needs of critically ill children who were undergoing increasingly extensive and complicated surgical procedures or recovering from complex medical problems.[1,2] In these early PICUs, anesthesiologists continued to provide the cardiorespiratory support and pain control that these patients required in the operating room. During the 1970s and 1980s, care teams involving surgeons, anesthesiologists, and pediatric subspecialists evolved, with the leader of that team being the pediatric intensivist. In the early years, these intensivists were largely derived from the ranks of pediatric anesthesiologists with the percentage of pediatricians becoming intensivists steadily increasing through the late 1980s and early 1990s. The Society of Critical Care Medicine (SCCM), which originated as an adult intensive care society, recognized pediatric critical care medicine as a discrete entity and created a separate section of pediatric critical care within the SCCM in 1981. Within 2 years, the section created guidelines defining the minimal requirements for pediatric ICUs. The American Board of Pediatrics sponsored the first pediatric critical care board exam in 1991. Although the majority of pediatric intensivists have completed a pediatrics residency prior to entering the field, many critical care divisions remain within departments of anesthesiology.[1–3]

## Indications for Intubation and Mechanical Ventilation

Mechanical ventilation of acutely ill children remains one of the principal therapies provided in PICUs throughout the United States. Available data from the Pediatric Health Information System (PHIS) database and other sources suggests that 20%–30% of all children admitted to PICUs across the United States receive invasive mechanical ventilation.[4,5] While respiratory disease in children is a major indication for endotracheal intubation and ventilation, these patients comprise only one-fifth of PICU admissions,[4] and there are numerous nonrespiratory indications for mechanical ventilation, including postoperative care and pain management, neurological and neuromuscular pathology, congenital heart disease, cardiomyopathy, and shock (Table 37.1).

**Table 37.1**

**Common Indications for Mechanical Ventilation**

| Primary Category | Primary Pathophysiologic Mechanism | Clinical Example |
|---|---|---|
| Respiratory causes | Restrictive pathology<br>(Decreased lung and/or chest wall compliance, low FRC) | Pneumonia<br>Acute respiratory distress syndrome<br>Atelectasis<br>Large pleural effusion or ascites<br>Severe scoliosis |
| | Obstructive pathology—upper airway | Croup<br>Epiglottitis |
| | Obstructive pathology—lower airway | Bronchiolitis<br>Asthma |
| CNS pathology | Poor or absent respiratory drive | Encephalitis |

| | | |
|---|---|---|
| | | Encephalopathy<br>Ingestion of medications<br>Electrolyte disturbance |
| | Inability to maintain airway | Poor or absent gag/cough |
| | Increased intracranial pressure | Traumatic brain injury |
| Neuromuscular pathology | Severe weakness | Electrolyte disturbance<br>Spinal muscular atrophy<br>Myasthenia gravis<br>Guillain-Barré syndrome<br>Tick paralysis<br>Spinal cord injury |
| | Weakness with inability to protect airway<br>Diaphragmatic paralysis<br>Flail chest | Infants disproportionately affected |
| Cardiovascular dysfunction | Severe shock<br>Severe myocardial dysfunction | |

There has recently been increasing emphasis on the use of noninvasive mechanical ventilation (NIV) in the form of continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BIPAP) to delay or avoid endotracheal intubation and invasive mechanical ventilation. Noninvasive mechanical ventilation is commonly used among adults with cardiogenic pulmonary edema, chronic obstructive pulmonary disease (COPD) exacerbation, and neuromuscular disorders.[7,8] Among preterm neonates with respiratory distress syndrome, noninvasive CPAP use is common and reduces the need for invasive mechanical ventilation.[9,10] No clear indications exist for the use of noninvasive modalities as a standard therapy among infants and children in PICUs. However, data suggest that its use is rapidly increasing, and more pediatric ICUs are adopting the use of NIV for managing mild to moderate acute respiratory failure[11] and in children with chronic conditions such as neuromuscular weakness (e.g., Duchenne's muscular dystrophy and spinal muscular atrophy) or restrictive lung disease. Acute conditions that are transient and self-limiting in nature may be amenable to noninvasive mechanical support and include upper airway obstruction (e.g., croup, postextubation upper airway edema), lower airway obstruction (e.g., asthma, bronchiolitis),[12,13] and lung parenchymal diseases such as bronchiolitis, pneumonia, or pulmonary edema. NIV does not afford a secure airway, and masks may impede airway clearance in the event of vomiting. NIV should therefore be used with caution in patients with poor neurologic function or with potential for rapid deterioration. Examples include severe trauma, cardiomyopathy, and septic shock. Underlying anatomical or airway anomalies that prevent the proper fitting of noninvasive interfaces also preclude the use of NIV.[8] Similarly, patients with respiratory failure following gastrointestinal tract surgeries or disruption of the integrity of the airway are rarely suitable candidates, as positive pressure could disrupt the surgical sites.

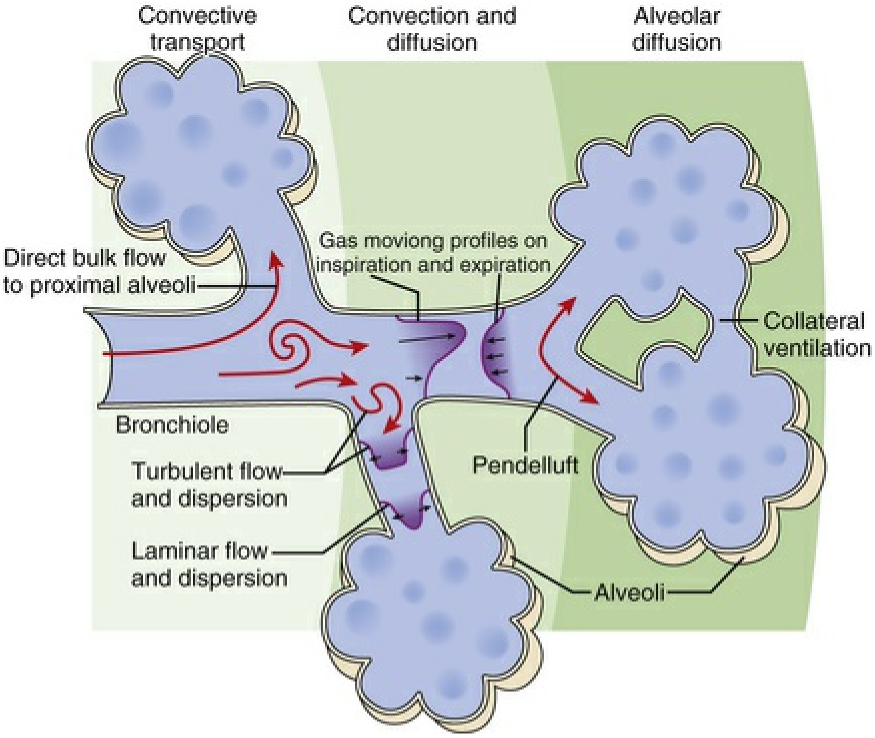
# Ventilation Strategies

## Conventional Versus Oscillatory Ventilation

PICUs worldwide use a wide variety of ventilation modes. Conventional ventilation modes cycle air or oxygen enriched gas mixtures through the respiratory tract by bulk airflow. Commonly employed modes include pressure control (PC), volume control (VC), or VC modes with decelerating flow that minimizes peak inspiratory pressures. These breaths are cycled using synchronized intermittent mandatory ventilation (SIMV) typically with pressure support for breaths above the set respiratory rate or assist control (AC) in which each breath above that rate is a controlled breath. Most modern ventilators also incorporate one or more support-modes or autoweaning support modes with embedded algorithms to ensure patient safety. Ventilators have traditionally synchronized breaths to patient effort using flow or pressure triggers. A newer innovation, neurally adjusted ventilator assist (NAVA) uses diaphragmatic electrical activity to initiate and terminate breath deliver and modulate flow.[14] Selection of a particular conventional ventilation mode is often not targeted specifically to the underlying disease but rather is determined by the intensive care physician's experience, local PICU policy and protocols, or outcomes of studies in adults.[15]

Less commonly used and unconventional modes of ventilation include high-frequency ventilation (HFV) and airway pressure release ventilation (APRV). High-frequency oscillatory ventilation (HFOV) is the predominant method of HFV used in the PICU setting, other methods being high-frequency jet ventilation, and high-frequency percussive ventilation (HFPV). High-frequency jet ventilators (HFJVs) contain flow interrupters that disrupt high velocity streams of gas, generating high-pressured jets that deliver small tidal volumes at supraphysiologic frequencies. HFPV delivers a series of high-frequency subtidal volumes in combination with low-frequency breathing cycles. HFPV may be defined as a time-cycled pressure-controlled ventilator coupled with a high-frequency flow generator. Most trials comparing HFV to conventional ventilation only assessed the role of oscillators; therefore, we only discuss the use of HFOV in further detail in this chapter.

During HFOV, airway pressure is maintained by constant gas flow (bias flow) through a valve that can be adjusted to increase or decrease mean airway pressure (MAP). Pressure waves are generated by a bellows that oscillates at supraphysiological ventilatory frequencies between 3 and 15 Hz (180–900 breaths per minute); the pattern of ventilation is akin to panting in dogs.[16,17] The oscillator creates both inspiratory and expiratory pressure waves, because the bellows is actively driven in both directions. Therefore, expiration is also active, which differentiates HFOV from conventional ventilators, HFJV and HFPV, where expiration is passive and dependent on the elastic recoil of the respiratory system. Active expiration may be beneficial in preventing hyperinflation and enhancing $CO_2$ elimination.[16] Tidal volumes generated with HFOV are smaller than the anatomic dead space. Therefore, unlike conventional ventilation, which relies principally upon bulk flow of gas to the alveoli, ventilation during HFOV is accomplished largely by enhanced gas mixing within the lung. The numerous mechanisms that account for the ability to achieve adequate ventilation with HFOV are outlined in Fig. 37.1, and include bulk convection, cardiac oscillations, Taylor dispersion, asymmetric velocity profiles, pendelluft, and diffusion.[17] For a detailed discussion on mechanical ventilation modes, please refer to Chapter 34, *Principles of Mechanical Ventilation.*



Convective transport
Convection and diffusion

Pendelluft
Laminar flow and dispersion
Alveoli

**FIG. 37.1** Gas-Transport Mechanisms during High-Frequency Ventilation (HFOV). There are several ways in which gas is transported during HFOV. These include (a) turbulent flow in larger airways, (b) bulk airflow in proximal alveolar units, (c) Pendelluft between adjacent alveolar units, (d) diffusion within alveolar units, (e) continuous streaming of gas into and out of alveolar units due to varying gas movement profiles on inspiration and expiration, and (f) Taylor Dispersion, the collateral ventilation of alveolar units through Pores of Kohn. (From Jean-Christophe Bouchut, M.D.; Jean Godard, M.D.; Olivier Claris, M.D. High-frequency Oscillatory Ventilation. Anesthesiology. Wolter's Kluwer 2014.)

Use of HFOV in the PICU was largely driven from positive studies on its use in the neonatal intensive care unit (NICU)[18]; however, recent large randomized control trials in adults have failed to show benefit.[19–21] Randomized controlled trials evaluating HFOV among children are lacking. A recently published retrospective observational study[22] and a propensity score matched secondary analysis of another pediatric RCT[23] compared early HFOV (initiated within 24–48 hours of intubation) to conventional mechanical ventilation and/or late HFOV. While the studies suggested increased duration of mechanical ventilation and mortality in HFOV groups, patients treated with HFOV also had poorer oxygenation than non-HFOV groups. Thus, the decision as to whether and when to initiate HFOV in the PICU is based more upon clinical experience than empiric evidence.

## Extracorporeal Membranous Oxygenation

Some PICU patients cannot be adequately oxygenated or ventilated using conventional ventilators or HFV. These PICU patients may be candidates for extracorporeal membrane oxygenation (ECMO). The ECMO circuit consists of a venous cannula situated in a large central vein or right atrium, a pump, an oxygenator, an arterial cannula with its tip in the aorta (for venoarterial ECMO) or right atrium (for venovenous ECMO); a bridge that permits flow to bypass the patient; connective tubing; ports for patient and circuit access; and continuous monitors of flow, oxygenation, hemoglobin, and other parameters.

As a rule, ECMO is considered only in patients with a reversible disease causing intractable hypoxemia or severe respiratory acidosis or who require an increase in cardiac output to achieve adequate end organ perfusion. The use of ECMO for severe hypercarbia without severe acidosis, for the prevention of ventilator induced lung injury, or for heart failure as a bridge to a ventricular assist device or heart transplant, is common but is perhaps less well accepted.

ECMO comes with its risks and complications. The ECMO circuit requires systemic anticoagulation, and the most common complication of ECMO remains hemorrhage, which can be from cannulation sites, surgical sites, sites of previous surgical procedures, or in the form of pulmonary and intracerebral hemorrhage.[24] Thromboembolism, infections, and disseminated intravascular coagulopathy are some other commonly encountered problems. Due to the high potential for associated morbidity, the threshold for cannulation in the setting of acute respiratory failure is relatively high. Oxygenation Index (OI) is a valuable measure of mechanical support required to maintain adequate oxygenation, and is measured by:

$$\mathrm{OI} = \frac{\text{mean airway pressure (cm } H_2O) \times FiO_2\ (\%)}{PaO_2\ \text{(mm Hg)}}$$

Recommendations from ECMOnet and Extracorporeal Life Support Organization (ELSO) recommend an OI > 30 or OI > 40, respectively, as indications for initiating ECMO support.[25] If OI is lower than 30 or 40, ECMO may be indicated in the setting of refractory air leak syndromes.[25] While a more extensive discussion of ECMO is beyond the scope of this chapter, suffice it to say, ECMO may be used to provide only gas exchange support (venovenous) or gas exchange and circulatory support (venoarterial). The pediatric pulmonologist should be aware that venovenous ECMO provides only partial gas exchange support and no circulatory support. Thus, oxyhemoglobin saturation values are typically in the 80%–90% range. Venoarterial ECMO can achieve complete cardiorespiratory support and oxyhemoglobin saturations typically are normal, but pulse oximetry may be unreliable, since pulsatile blood flow may be minimal or absent. Bronchoscopy is often required prior to ECMO discontinuation to perform bronchoalveolar lavage and clear mucus plugs that may accumulate while the child is on rest ventilator settings. While anticoagulation certainly increases the risk of bleeding during invasive procedures, successful weaning off ECMO often requires one or more bronchoscopies.

## Complications of Mechanical Ventilation

### Mucus Plugging

A common problem encountered among mechanically ventilated patients is secretion management. Multiple factors in the ICU place mechanically ventilated children at an increased risk for retained secretions. The inflated endotracheal tube (ETT) cuff causes significant depression of tracheal mucus velocity and disrupts the mucociliary escalator.[26] Furthermore, defects in ciliary function are likely underappreciated and are probably a greater contributor to respiratory failure in the PICU than commonly appreciated (see

Chapter 71, *Primary Ciliary Dyskinesia*). The relative immobility and muscular weakness associated with prolonged ICU admissions contributes to weakened cough and pooling of secretions, and depression of spontaneous breathing through the use of sedatives and paralytics compounds the problem by impairing mucociliary clearance and cough reflexes. Fluid restriction and aggressive diuresis also contribute to thickened secretions.[27] Smaller airways in children are especially prone to obstruction by thick, immobile secretions, contributing to ventilation-perfusion (V/Q) mismatch and further worsening of respiratory failure. Acute decompensation can occur if endotracheal tubes or tracheostomy tubes become obstructed with mucus, and suctioning or ETT exchange may be required. Strategies to minimize and treat mucus plugging include humidification, the use of mucolytics, and mechanical disruption of mucus.

Perhaps the simplest and most intuitive medicinal therapy is to ensure adequate humidification of the ventilator circuit. There is clear evidence that drying of the mucosal surface causes mucus adhesion to the epithelium,[28] and heating and humidifying cool medical gases has now become a standard of care during mechanical ventilation.[29] However, the optimum degree of humidification is frequently debated and there are no straightforward or agreed upon methods for monitoring the adequacy of humidification.[30] Secretion volume and consistency, frequency of ETT occlusion, changes in ETT diameter and/or resistance, and suction frequency are often used as surrogate markers for adequate humidification. However, none of these variables are very reliable as they are easily influenced by underlying disease process or concurrent therapies.

Along with standard methods of humidification, nebulization with hypertonic saline (HS, 3% or greater) is frequently used for airway clearance in the setting of thick tenacious secretions that are difficult to suction. Use of hyperosmolar agents such as HS and mannitol was initially studied in patients with cystic fibrosis (CF) and bronchiectasis and showed significant benefit in that population,[31,32] leading to wider use among mechanically ventilated patients in pediatric ICUs. Theoretically, inhaled HS generates transient osmotic gradients on airway surfaces, drawing water from the submucosal space onto the airway surface.[28] This increased water in the airway lumen reduces the entanglements of the mucin network, thus facilitating mucociliary clearance. Furthermore, in sputum studies, a reduction in the viscoelastic properties, surface tension, and spinability and an increase in the hydration of mucus have been measured in response to HS.[31]

Other adjunctive agents used to treat or prevent mucus plugging include mucolytic agents such as N-acetylcysteine (NAC) and recombinant human deoxyribonuclease (rhDNase). NAC disrupts disulfide bonds that link mucin oligomers and has antioxidant and antiinflammatory properties.[33] NAC was first described as a mucolytic agent in 1963.[34] Several clinical studies were undertaken following the discovery and its use became widespread, particularly among the CF population. Several subsequent trials have failed to show any benefit of using NAC among patients with acute respiratory distress syndrome, ARDS (as well as CF) and a recent meta-analysis of ARDS trials concurred.[35] However, in the setting of mucus hypersecretion and plugging among mechanically ventilated children, its use as a rescue therapy continues due to the lack of clear evidence disproving its efficacy.

DNase is a recombinant endonuclease that cleaves DNA. Its use in the PICU is generally restricted to conditions with purulent respiratory secretions[33] and its use is currently US Food and Drug Administration (FDA) approved in the United States for the treatment of CF lung disease. Multiple studies have evaluated the use of DNase in critical care settings for treatment of atelectasis secondary to mucus plugging in mechanically ventilated patients. Most of these are small underpowered studies, and their findings seem mixed.[36–39] A recent meta-analysis also recognized the low quality and quantity of existing data,[40] and like NAC, it continues to be used in select patients with thick purulent secretions.

Several mechanical airway clearance techniques are commonly used in the PICU: chest physiotherapy (CPT), intermittent percussive ventilation (IPV), and mechanical insufflation-exsufflation. CPT has been advocated in the field of pediatrics for many years now and is the traditional first-line therapy for secretion management and atelectasis.[41] Several CPT techniques are described and used in mechanically ventilated children: (1) manual percussion with cupping of hand or with a facemask, (2) vibration of the chest wall transmitting energy through the chest wall to loosen or move bronchial secretions, and (3) postural drainage using gravity to move secretions from peripheral airways to the larger bronchi.[42] Despite its historical status and widespread use, evidence for CPT remains weak or absent,[43] and it is not recommended as a routine treatment by the American Association of Respiratory Care.[44]

IPV involves application of high-frequency oscillations to the airways, enhancing secretion clearance when interfaced with conventional mechanical ventilation. The mechanism by which IPV may promote pulmonary secretion clearance is its asymmetrical flow pattern, whereby expiratory flow exceeds inspiratory flow to propel secretions forward.[45] It can be an effective tool in mechanically ventilated patients with refractory atelectasis secondary to mucus plugging. In a small randomized controlled trial, use of IPV in mechanically ventilated pediatric patients produced more clinically important improvement in atelectasis than was observed in children receiving CPT.[46]

Mechanical insufflation-exsufflation, more commonly known as cough-assist, was first introduced in the 1950s, but its use became more widespread in the 1990s. It functions by mechanically inflating the lungs with positive pressure, followed by the rapid application of negative pressure that stimulates a cough. Similar to IPV, cough-assist devices create shear forces in the airway that help mobilize secretions. Typically, positive and negative pressure swings of 30–40 cm $H_2O$ are applied in repetitions of 3–5 maneuvers to mobilize secretions.[45] This therapy has been used primarily to promote pulmonary hygiene in patients with neuromuscular diseases and is one of the few therapies that are recommended by the American Association of Respiratory Care.[44] It should be used with caution in PICU patients prone to lung derecruitment.

## Atelectasis

Atelectasis occurs when airway pressure declines below the critical closing pressure of a given terminal respiratory unit. In a healthy lung, this closing pressure is below atmospheric pressure, but in disease states, it becomes elevated. To reverse atelectasis, airway pressure must be raised higher than the critical opening pressure. This pressure is again elevated in many disease states. Since lung disease in many PICU patients is heterogeneous, maintaining recruitment of one lung region may result in overdistention or injury to another. Mucus plugging may also contribute to atelectasis and should be treated as discussed in the previous section.

The atelectasis present in many PICU patients compromises oxygenation and ventilation secondary to V/Q mismatching. Additionally, pooling of secretions in atelectatic lung segments may also predispose the patient to nosocomial pneumonia.[47] Mucus plugging is probably the commonest cause of atelectasis as discussed above. Other causes of atelectasis include foreign body aspiration, aspiration of secretions or gastric contents, and the regional atelectasis that occurs as a consequence of ARDS.

Nonpulmonary factors often contribute to atelectasis. In the supine patient, abdominal contents push in a cephalad direction, decreasing the functional residual capacity. Complete or partial closure of alveoli in the dependent lung zones results in reduced compliance and increased risk of atelectasis. The most common segment of the lung to develop atelectasis is the left lower lobe, possibly due to compression by the heart in the supine position and its poor drainage.[48] In such cases, atelectasis frequently responds to judicious use of positive end-expiratory pressure (PEEP) that overcomes the closing pressure of smaller airways and thus “stents” them open. PEEP titration studies can be employed at the bedside to determine optimal PEEP that produces maximal lung recruitment and minimizes dead space ventilation.[49] Similarly, recruitment maneuvers can be employed to expand atelectatic lung segments. These maneuvers involve application of elevated airway pressure to increase transpulmonary pressure transiently. This could be through sustained inflation, intermittent sighs, or stepwise increases of PEEP or airway inspiratory pressure. Several studies have demonstrated improvements in oxygenation, lung mechanics, and lung reaeration after application of recruitment maneuvers, but the optimum method of recruitment and the impact on clinical outcome remains under discussion.[50]

The pediatric pulmonologist is commonly consulted in PICU patients with refractory atelectasis due to mucus plugging who may need therapeutic bronchoscopy. Numerous case series have shown fiberoptic bronchoscopy to be moderately effective in recruiting atelectatic lung segments by suctioning secretions under direct visualization.[47] However, it must be recognized that ICU patients might be too unstable from a hemodynamic or respiratory standpoint to undergo bronchoscopy. A significant decrease in $PaO_2$ and elevation in $PaCO_2$, as well as increased auto-PEEP leading to reduced venous return and cardiac output, can be seen during bronchoscopy, and this decline is more pronounced as the duration and amount of suctioning is increased.[47,51] Hypoxemia eventually returns to baseline but takes up to 15 minutes in patients with healthy lungs and several hours in those patients with parenchymal disease.[47,51] Studies have also shown elevations in intracranial pressure (ICP) with bronchoscopy despite heavy sedation and paralysis. Decisions regarding bronchoscopy in patients with intracranial pathologies should be made with this information in mind. Importantly, the cause of atelectasis should be established before proceeding with bronchoscopy. While mucus plugging may be amenable to bronchoscopic intervention, atelectasis from other causes (e.g., bronchial compression due to an enlarged cardiac chamber, diaphragmatic dysfunction, and pleural effusion) would not benefit from bronchoscopy. Additionally, while bronchoscopy may temporarily improve atelectasis in patients with severe bronchomalacia or restrictive lung disease, the procedure should be part of a larger respiratory care plan aimed at maintaining lung recruitment. Refer to Chapter 9, *Bronchoscopy and Bronchoalveolar Lavage in Pediatric Patients,* for further details.

## Ventilator-Induced Lung Injury

Although mechanical ventilation is essential for supporting many patients, it may itself cause lung damage, particularly in disease states such as acute respiratory distress syndrome ARDS, leading to ventilator-induced lung injury (VILI). The development of VILI is triggered by regional overdistension of the alveoli (volutrauma), high airway and alveolar pressures (barotrauma), cyclic opening and collapse of terminal respiratory units (atelectrauma), and inflammatory cell recruitment due to high shear (biotrauma). Barotrauma can manifest as air leaks causing pneumothorax, pneumomediastinum, interlobular emphysema, or subcutaneous emphysema of the face, neck, or chest wall.[52] Barotrauma was the first widely recognized component of VILI and remained unquestioned until the 1980s when Dreyfuss et al. showed that application of high tidal volume and not airway pressure was the major determinant of VILI, introducing the concept of volutrauma.[53] Additionally, heterogeneity of lung compliance in conditions such as ARDS can aggravate the development of VILI as repeated opening and closing of short time constant lung units renders adjacent zones susceptible to shear stresses, creating a vicious cycle of VILI, both at high and low tidal volumes (atelectrauma). A relatively newer concept is that of biotrauma, which suggests that even in the absence of overt tissue injury, such as that caused by barotrauma, unphysiological shear or stress can promote release of proinflammatory cytokines and recruitment of white cells, with resulting lung inflammation.[54]

The application of generous PEEP can be useful in keeping lung segments well recruited and thus avoid atelectrauma. The optimum PEEP level remains unclear and likely varies between individual patients, but several randomized controlled trials and meta-analyses have failed to demonstrate any mortality benefit of using higher levels of PEEP (>12 cm $H_2O$).[52] The term "open lung ventilation" is often used to describe the strategy of using higher PEEP to prevent atelectrauma. HFV also offers the advantage of open lung ventilation; continuous and relatively high mean airway pressures keep the alveoli patent at all times as small tidal volumes are administered. As a general rule, pediatric intensivists titrate PEEP or MAP so that at end inspiration the lung is inflated to the approximate volume of the patient's baseline functional residual capacity.

An understanding of the above mechanisms has led to evidence-based efforts to reduce VILI and produced recommendations for "lung-protective" ventilation strategies, including the use of low tidal volumes and generous PEEP, limiting plateau pressures, and using permissive hypercarbia. The use of lower tidal volumes reduces end-inspiratory stress/strain and theoretically prevents volutrauma. The landmark ARDSnet trial of 2000 compared mechanical ventilation with low tidal volume (6 mL/kg) versus high tidal volume (12 mL/kg) ventilation among adults and successfully established the benefits of lower tidal volume resulting in decreased mortality and an increased number of ventilator-free days.[55] Refer to Chapter 38, *Acute Respiratory Distress Syndrome* for further discussion on ARDS and lung protective strategies.

It is important to realize that children in the ICU may have disease processes (pulmonary or otherwise) that prevent optimal ventilation. In such scenarios, escalation of inspiratory pressures would likely improve gas exchange but would also induce barotrauma in the process and prove harmful in the long run. In these situations, it is advisable to limit plateau pressures to 30–35 cm $H_2O$ and accept higher carbon dioxide levels. While practicing "permissive hypercarbia," care must be taken to avoid severe respiratory acidosis, particularly in hemodynamically unstable children. Ventilator management in PICU patients commonly involves tradeoffs not necessary outside of the PICU, and strategies are dependent upon careful risk-benefit analysis considered in the context of each patient.

## Air Leak Syndromes

Pneumothorax, pneumomediastinum, and subcutaneous emphysema are common air leak syndromes observed in the PICU. One of the commonest causes is aggressive mechanical ventilation and resulting barotrauma or volutrauma with breach of airway integrity. Mechanical ventilation of children with obstructive lung physiology (e.g., asthma, or bronchiolitis obliterans) can also pose challenges with inadequate expiratory flow and resulting hyperinflation, which can cause air leaks. This can occur with both invasive and noninvasive mechanical ventilation. Other causes of air leak include trauma, necrotizing infection, surgical procedure, or endoscopic tracheal and esophageal procedure (Fig. 37.2).

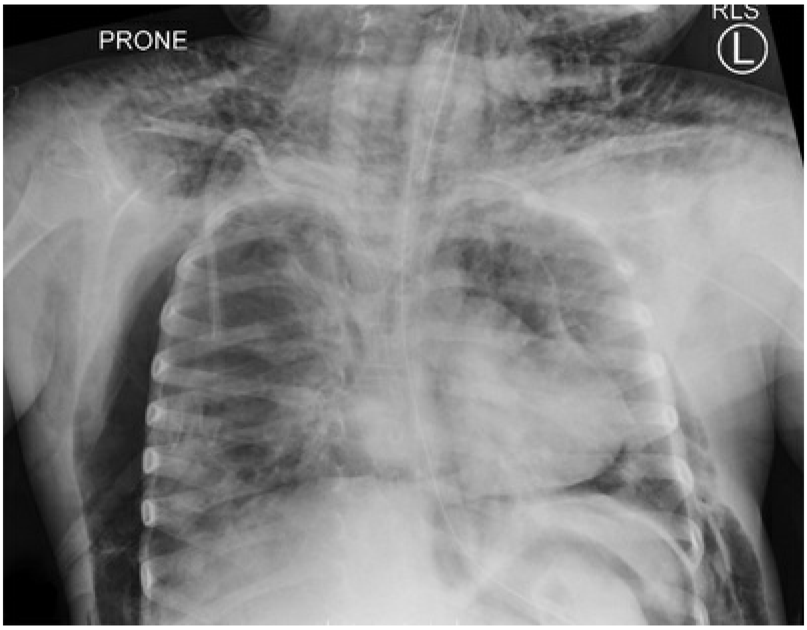

**FIG. 37.2** Chest x-ray of a mechanically ventilated child with pneumomediastinum, and severe subcutaneous emphysema of the chest wall and neck.

While subcutaneous emphysema can be cosmetically disconcerting, it does not have any life-threatening implications. Adult studies have evaluated the use of subcutaneous fenestrated catheters or fenestrated angiocatheters for treatment,[56] but there is a significant risk of infections associated with these invasive devices and the management strategy in pediatric ICUs is conservative, with treatment of the underlying disease process and possibly chest tube placement.

Similarly, pneumomediastinum is rarely clinically significant. It is generally considered a benign entity of little clinical importance with a good prognosis.[57] There are only rare reported cases of severe pneumomediastinum causing vessel or tracheal obstruction and inducing the symptoms and signs of tamponade and decreased venous return. Management, therefore, is mainly conservative and primarily involves limiting airway pressures.[57]

Pneumothorax, if large enough, can cause respiratory and hemodynamic compromise and is commonly the cause of pneumomediastinum and subcutaneous emphysema. Treatment of pneumothoraces may involve urgent needle thoracostomy (most safely performed in the second intercostal space in the midclavicular line) and chest tube placement. Measures should be made to prevent further alveolar injury by limiting airway pressures, allowing spontaneous healing of injured alveoli and resolution of air leak. A large unilateral air leak may make ventilation of the healthy lung difficult and require selective mainstem bronchus intubation, typically performed with bronchoscopic guidance. Refractory air leak can be treated with temporary bronchial occlusion using fibrin glues or complete lung rest using ECMO. Persistent but medically manageable air leak may be treated with pleurodesis and persistent difficult to manage air leak may require lobectomy.

## Ventilator-Associated Pneumonia

In recent years, ventilator-associated pneumonia (VAP) has gained significant attention due to the associated mortality and morbidity, and it is now believed to be the second most common hospital acquired infection in PICUs, with some studies reporting incidences as high as 20%.[58] There has also been an increasing recognition of the financial and socioeconomic burden from prolonged mechanical ventilation and extended hospital stays associated with VAP, and the Centers for Disease Control and Prevention (CDC) report the average attributable patient cost of VAP ranging from $11,897[59] to $25,072.[60]

Pathogenesis of VAP remains unclear: it is likely the result of microaspiration, but in immunocompromised patients or patients with mucosal breakdown (e.g., burn patients), it may be secondary to lung infiltration from the bloodstream. Entry of bacteria to the lung may also be facilitated directly through the ETT during disconnection from the ventilator circuit. Most of the bacteria found in the endotracheal aspirates of patients suffering from VAP are also found in the naso-oropharynx and even in gastric secretions. Most commonly implicated organisms include *Staphylococcus aureus, Streptococcus pneumoniae, Haemophilus influenzae, Pseudomonas aeruginosa, Acinetobacter sp., Stenotrophomonas maltophilia* and enteric gram-negative bacilli including *Enterobacter sp., Klebsiella sp. and Citrobacter sp.*[58,61]

Diagnosing VAP can be challenging, as universally accepted criteria are lacking, and the definition and surveillance published by CDC remain the most commonly accepted approach. It is defined as a pneumonia occurring after the patient has been intubated and received mechanical ventilation for at least 48 hours. The initial diagnosis is based on clinical suspicion and the presence of at least one of the following on two or more serial chest radiographs: new or progressive radiographic infiltrates, consolidation, cavitation, and pneumatoceles in an infant 1-year-old or above. Additionally, the standard diagnostic criteria include at least two or three (applicable only for the under 12-year-olds) of the following: fever of greater than 38°C or hypothermia of less than 36.5°C; change in sputum volume or character, or increased suctioning requirement; new onset or worsening cough, dyspnea, tachypnea or apnea; rales, bronchial breath sounds, wheezing or rhonchi.[58] Other criteria for diagnosis of VAP include worsening gas exchange or increased ventilator demand after a period of stability and the use of serum biomarkers such as C-reactive protein (CRP) or procalcitonin to narrow the diagnostic margin.[62]

Caution must be exercised when diagnosing VAP. The above-mentioned signs and symptoms may also be present in conditions other than VAP (e.g., presence of increased secretions with tracheobronchitis, or radiographic findings with atelectasis). There is debate as to whether to include cultures of endotracheal secretions, since a positive culture result may represent colonization rather than true infection, potentially leading to inappropriate antibiotic use with the ever-present risk of selection of antibiotic-resistant, particularly Gram negative, bacteria.

Efforts to minimize VAP in children have focused on preventive strategies that include hand hygiene, mouth care with antiseptic solution, elevating the head of the bed by 30–45 degrees, changing ventilator circuits only as needed, minimizing patient-ventilator disconnections with in-line suctioning, frequent drainage of ventilator condensate away from the ETT, ETT cuff pressure maintenance, monitoring of gastric residuals to prevent aspiration, and minimizing ventilator days by adopting sedation holidays and weaning protocols. Since VAP pathophysiology is multifactorial, strategies for prevention are commonly implemented in bundles and not with each individual preventive measure in isolation.[58] Table 37.2 reviews key studies that have studied and shown success with pediatric VAP bundles.

## Table 37.2

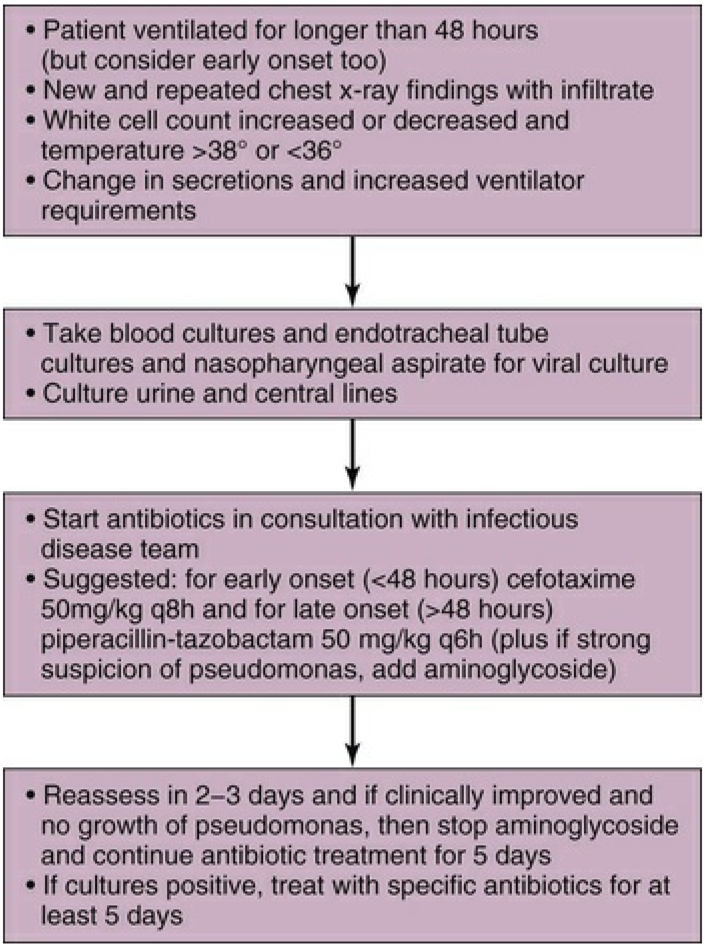
## What Key Interventions Have Been Used for Pediatric VAP Bundle?

| | | |
|---|---|---|
| Brierley et al.[104] | ▪ Head up tilt (target 45°, but achieved 20°–30°)<br>▪ Mouth care with oral antiseptic every 4 hourly OR 12 hourly toothbrush<br>▪ Clean suctioning practice<br>▪ Gastric ulcer prophylaxis: Ranitidine<br>▪ Chest x-ray interpretation<br>▪ Documentation to be completed 4 hourly<br>▪ Indication of VAP compliance, to be documented each shift | Prebundle VAP was 5.6/1000 ventilator days.<br>Postbundle VAP was 0/1000 ventilator days over 12-month period. |
| Bigham et al.[105] | ▪ Prevention of bacterial colonization of oropharynx, stomach and sinuses<br>▪ Change ventilator circuits and in-line suction catheters only when visibly soiled<br>▪ Drain condensate from ventilator circuit at least every 2–4 h (use heated wire circuits to reduce rainout)<br>▪ Store oral suction devices (when not in use) in nonsealed plastic bag at the bedside; rinse after use<br>▪ Hand hygiene before and after contact with ventilator circuit<br>▪ When soiling from respiratory secretions is anticipated, wear gown before providing care to patient<br>▪ Follow unit mouth care policy every 2–4 h | The VAP rate was reduced from 5.6 to 0.3 infections per 1000 ventilator days after bundle implementation. |
| Rosenthal et al.[106] | ▪ Prevention of aspiration of contaminated secretions<br>▪ Elevate HOB 30°–45° unless contraindicated and by written order<br>▪ Always drain ventilator circuit before repositioning patient<br>▪ When possible, for children > 12 years old, use endotracheal tube with dorsal lumen above endotracheal cuff to help suction secretions above the cuff<br>▪ Adherence to hand hygiene guidelines<br>▪ Semirecumbent position 30°–45°<br>▪ Daily assessment to wean and use of weaning protocols<br>▪ Use of noninvasive ventilation whenever possible, minimizing the duration of ventilation<br>▪ Preference of orotracheal intubation over nasotracheal intubation<br>▪ Maintenance of endotracheal cuff pressure of at least 20 cm $H_2O$<br>▪ Removal of condensate from ventilator | VAP rate was 11.7/1000 ventilator days during baseline period and 8.1/1000 ventilator days during the intervention period (31% reduction in VAP rate). |

| | | |
|---|---|---|
| | circuits, keeping the ventilator closed during condensate removal<br>▪ Changing of the ventilator circuit only when visibly soiled or malfunctioning<br>▪ Avoidance of gastric over distension<br>▪ Avoidance of histamine-receptor 2-blocking agents and proton pump inhibitors<br>▪ Use of sterile water to rinse reusable respiratory equipment | |

Review of key studies and interventions that have been used for pediatric VAP bundles. Table modified from Chang I, Schibler A. Ventilator associated pneumonia in children. *Paediatr Respir Rev.* 2015;20:10-16, with permission.

Clinical suspicion for VAP mandates early antimicrobial treatment. If the initial choice of antibiotics is inappropriate, or there are significant delays in initiation of therapy, there may be significant morbidity or mortality associated with the VAP episode.[61,63] Pediatric intensivists and pulmonologists should collaborate with infectious disease experts within their own hospitals to develop specific algorithms for treating VAP based on hospital bacterial resistance patterns. While debate continues on the duration of antibiotic therapy for VAP, data suggest that shorter therapies may be equally effective as prolonged antibiotic courses.[64] Fig. 37.3 presents a simplified algorithm for treatment of VAP. Early bronchoalveolar lavage should be considered to help direct VAP treatment. Protected specimen brush culture can also be useful for diagnosis. While endotracheal cultures may represent either ventilator-associated tracheitis or VAP, protected specimen brush cultures are only consistent with VAP.[65] However, there is a lack of data in children that would support the routine use of protected specimen brush.



- Patient ventilated for longer than 48 hours (but consider early onset too)
- New and repeated chest x-ray findings with infiltrate
- White cell count increased or decreased and temperature >38° or <36°
- Change in secretions and increased ventilator requirements

- Take blood cultures and endotracheal tube cultures and nasopharyngeal aspirate for viral culture
- Culture urine and central lines

- Start antibiotics in consultation with infectious disease team
- Suggested: for early onset (<48 hours) cefotaxime 50mg/kg q8h and for late onset (>48 hours) piperacillin-tazobactam 50 mg/kg q6h (plus if strong suspicion of pseudomonas, add aminoglycoside)

- Reassess in 2–3 days and if clinically improved and no growth of pseudomonas, then stop aminoglycoside and continue antibiotic treatment for 5 days
- If cultures positive, treat with specific antibiotics for at least 5 days

**FIG. 37.3** Suggested approach to diagnose and treat VAP. (Modified from Chang I, Schibler A. Ventilator associated pneumonia in children. *Paediatr Respir Rev.* 2015;20:10-16, with permission.)

## Special Pulmonary Consideration in Pediatric Patients With Neuromuscular Disorders

Children with neuromuscular diseases (e.g., muscular dystrophy and spinal muscular atrophy) have limited respiratory system reserve at baseline and are at elevated risk of respiratory failure. Relatively benign upper respiratory tract infections can progress to increased secretion retention, secondary bacterial infection, and an acute respiratory deterioration. Because of their fragile respiratory status, postoperative ICU admission should be considered when children with neuromuscular disease undergo elective surgery.[66,67]

As a general rule, patients with neuromuscular disorders admitted to the ICU with or in anticipation of respiratory compromise should have early or preventative institution of airway clearance and NIV to maintain lung recruitment and minimize retained secretions. Evidence suggests that noninvasive positive pressure ventilation (PPV) in patients with neuromuscular weakness can improve tachypnea, dyspnea, and work of breathing; increase alveolar ventilation; help reexpand the lung bases; and provide respiratory muscle rest.[68] As the patient improves, these therapies can be weaned.

Noninvasive PPV support may be inadequate in the setting of severe respiratory failure. Patients with neuromuscular disorders may require invasive respiratory support for the first few days of critical illness, but the goal should always be to extubate at the earliest opportunity. Aggressive airway clearance should be continued, and early bronchoscopy should be pursued in the event of persistent infiltrates or atelectasis. As a general rule, patients with neuromuscular disease should be extubated directly to continuous NIV, even if their pulmonary function parameters suggest a high likelihood of successful extubation.[66] Before proceeding with trial of extubation in spinal muscular atrophy patients, it is advisable to ensure that these patients are afebrile and do not require supplemental oxygen, and their chest radiograph should not demonstrate atelectasis or infiltrates.[69] These weaning criteria are unique to this group of patients; in no other group is there the stringent requirement for normal gas exchange in room air before extubation. Since pediatric pulmonologists often have long-standing relationships with these patients and their families, early and frequent discussions regarding extubation criteria are essential. Patients with lesser degrees of muscle weakness can be extubated while they still have increased respiratory support requirements.

## Pulmonary Hemorrhage

Severe pulmonary hemorrhage is a rare but dramatic reason for ICU admission. The causes can be varied, and include infections, CF, bronchiectasis, trauma, congenital heart disease, arteriovenous collaterals, pulmonary hypertension, pulmonary embolism, tumors, idiopathic pulmonary hemosiderosis, and vasculitides such as systemic lupus erythematosus (SLE), Goodpasture's syndrome, Wegener's syndrome, and Henoch-Schonlein purpura.[70] Definitive diagnosis may require extensive studies such as serology, echocardiogram, computed tomography (CT) scan with contrast, and tissue biopsy via transbronchial biopsy, thoracotomy, or video assisted thoracoscopic surgery (VATS). Many of these patients may present with severe hypoxemic respiratory failure and require resuscitation and stabilization. Once mechanical ventilation is initiated, it is common practice to maintain high MAP and high PEEP to "tamponade" bleeding from smaller and relatively compressible capillaries. Use of HFOV can also be useful in this circumstance to deliver a constant elevated MAP. If there is strong suspicion of vasculitic disorders, evidence suggests early use of high-dose corticosteroids.[71–73] Diffuse alveolar hemorrhage in children is discussed further in Chapter 61.

## Intensive Care Unit Neuromyopathy

Neuromyopathy in the ICU has been widely recognized and researched among adults but often remains underdiagnosed among children.[74] Both critical illness and its associated treatments lead to muscle and nerve injury.[75] Prolonged immobility and bed rest is common in pediatric ICUs and leads to disuse atrophy secondary to decreased muscle protein synthesis and increased muscle catabolism.[76,77] Furthermore, the interaction of critical illness with immobility may lead to even greater muscle loss,[78] likely secondary to protein catabolism and neurotoxicity induced by proinflammatory cytokines.[75]

A common iatrogenic cause of neuromyopathy in the PICU is the concomitant use of corticosteroids and muscle relaxants (particularly curare derivatives such as rocuronium and vecuronium), which are agents that are commonly administered together in children with severe protracted ARDS or status asthmaticus. Aminoglycoside antibiotics have also been associated with neuromyopathy in the ICU, but the evidence remains mixed.[79]

The implications for children with ICU acquired neuromyopathy can be quite serious. The resultant muscular weakness, particularly involving the respiratory muscles, can lead to prolonged or failed weaning from mechanical ventilation. Acquired ICU neuromyopathy can prolong hospitalization and necessitate continued mechanical ventilation during rehabilitation.[75,79] Ambulation while still receiving mechanical ventilation, in-bed exercise, and early physical therapy are becoming more common in adult ICUs[80,81] and may soon gain acceptance in PICUs as a means to minimize this complication of ICU care. Rehabilitation and conditioning associated with early ambulation can also have positive implications for patients awaiting lung transplantation, as shown among children on ECMO support.[82]

## Special Pulmonary Considerations in Pediatric Patients With Congenital Heart Disease

Management of children with congenital heart diseases or heart failure in the PICU can pose special challenges for intensivists and pulmonologists due to the unique cardiopulmonary interactions at play. Of particular interest are children who have undergone palliative surgery for single ventricle physiology. The goal of palliation in single ventricle congenital heart disease is to reduce ventricular work and maintain a balanced pulmonary and systemic circulation by transitioning the heart from dual circulation (pulmonary and systemic) to single circulation physiology. To achieve this, the superior vena cava (Glenn procedure) or superior and inferior vena cava (Fontan procedure) drain into the pulmonary artery with the main pulmonary artery disconnected from the pulmonary trunk. For details on how this is achieved in different congenital heart lesions, we refer the reader to an excellent textbook.[83] Negative intrathoracic pressure during spontaneous ventilation facilitates venous return, leading to increased pulmonary blood flow and cardiac output.[84] Conversely, positive pressure ventilation impedes venous return and decreases cardiac output. In the setting of passive blood flow to the lungs, pulmonary vascular resistance (PVR) is also an important factor limiting pulmonary blood flow and cardiac output. Permissive hypercarbia may increase PVR. The need to both maintain lung recruitment and pulmonary blood flow should be considered when providing mechanical ventilatory support in the ICU to children with single ventricle physiology. The MAP, tidal volume, and minute ventilation need to be adequately titrated so as to offset the effects of hypercarbia, hypoxemia, and reduced lung volumes that may increase PVR and impede pulmonary blood flow.[85] However, if the MAP is maintained too high, the elevated intrathoracic pressure can impede venous return and lung overdistension can increase PVR, both leading to decreased pulmonary blood flow and decreased cardiac output. Negative pressure ventilation via use of a cuirass has also been shown to improve pulmonary blood flow and cardiac output in patients with single ventricle physiology;[84,86,87] however, this technology is not available in many PICUs. Early extubation and transition to spontaneous ventilation after Fontan surgery has been shown to improve outcomes and length of hospital stay and should be actively pursued.[88,89] If continued mechanical ventilation is necessary, APRV has been shown to improve pulmonary blood flow, which is likely secondary to negative dips in intrathoracic pressure that are observed with APRV but not with conventional modes of mechanical ventilation.[90]

In addition to the cardiopulmonary interactions at play, children recovering in the ICU after congenital heart disease repair also need to be observed for postoperative complications that are specific to cardiac surgeries. Of particular concern are vocal cord dysfunction (from recurrent laryngeal nerve injury during aortic arch repairs) and diaphragmatic paralysis (from phrenic nerve injury). For this reason, failure to extubate in this population should always raise concern for phrenic nerve injury, and fluoroscopic studies may be needed to assess diaphragmatic motion. Once extubated, a formal swallow evaluation should be considered prior any attempts at oral feeding to rule out aspiration secondary to vocal cord dysfunction. Chylothorax secondary to intraoperative thoracic duct injury may also occur in these children. A chest tube may be needed to evacuate the chylous effusion, and feeding should consist of a low-fat formula to minimize chyle production and allow spontaneous healing.[91] Octreotide is another common but unproven therapy for chylothorax. Successful use of octreotide has been reported in several case reports, but no randomized controlled trials have been conducted to date.[92]

# Special Pulmonary Considerations in Pediatric Patients With Malignancy or Hematopoietic Stem Cell Transplantation

Acute respiratory failure secondary to acute lung injury is a common indication for PICU admission after hematopoietic stem cell transplant (HSCT). Depending on the HSCT center involved, 20%–30% of children receiving HSCT may require intubation and mechanical ventilation,[93,94] and among these patients, mortality is as high as 60% during PICU admission and 74% at 180 days after PICU discharge.[95] Table 37.3 shows that the causes of lung injury in the posttransplant setting can be broadly divided into infectious vs. noninfectious and early (within 100 days of transplant) vs. late (more than 100 days following transplant). Advances in preemptive and prophylactic therapy to prevent respiratory infections during the immune deficient state following HSCT have resulted in a decreasing incidence and proportion of infectious versus noninfectious respiratory complications,[96] but vigilance and timely initiation of therapy remains the key.

## Table 37.3

**Causes of Lung Injury and Respiratory Failure After Stem Cell Transplant**

| Early (Day 0–100) | Late (Day 100+) |
|---|---|
| NONINFECTIOUS CAUSES | NONINFECTIOUS CAUSES |
| Pulmonary edema | Bronchiolitis obliterans |
| Periengraftment respiratory distress syndrome | Bronchiolitis obliterans organizing pneumonia |
| Diffuse alveolar hemorrhage | Delayed pulmonary toxicity syndrome |
| Acute interstitial pneumonitis | Chronic GVHD |
| TA-TMA | — |
| TRALI | — |
| INFECTIOUS CAUSES | INFECTIOUS CAUSES |
| Bacteria: Gram-negative rods and Gram-positive cocci | Bacteria: Encapsulated bacteria, Gram-negative rods and Gram-positive cocci |
| Virus: HSV, CMV, adenovirus, HHV6, RSV, influenza, parainfluenza, rhinovirus, human metapneumovirus | Virus: adenovirus, CMV, VZV, Epstein-Barr virus |
| Fungi: Candida, aspergillus, pneumocystis | Fungi: Candida, aspergillus, pneumocystis |

*CMV*, Cytomegalovirus, *HHV6*, human herpesvirus type 6; *HSV*, herpes simplex virus, *RSV*, respiratory syncytial virus; *TRALI*, transfusion related acute lung injury; *VZV*, varicella zoster virus.

Modified from Chima RS, Abulebda K, Jodele S. Advances in critical care of the pediatric hematopoietic stem cell transplant patient. *Pediatr Clin North Am.* 2013;60(3):689-707, with permission.

Clinical studies have established a strong association between graft-versus-host disease (GVHD) and noninfectious lung injury. The acute inflammation and cellular infiltration into the lung parenchyma during acute GVHD has been implicated in development of restrictive lung disease and idiopathic pneumonia syndrome (IPS) pathogenesis,[97] whereas chronic GVHD has been linked to progressive obstructive lung disease and bronchiolitis obliterans.[98] In a subset of HSCT patients, extensive pulmonary vascular disease secondary to transplant-associated thrombotic microangiopathy (TA-TMA) may be observed, with resulting pulmonary hypertension and hypoxemic respiratory failure.[99] Therefore, TA-TMA should be suspected in patients with reassuring imaging studies that present with unexplained hypoxemia.

Viral, bacterial, and fungal cultures should be performed to identify potential infections, and bronchoalveolar lavage should be considered early during ICU admission. In addition to simple chest radiographs, detailed imaging in the form of CT scan and echocardiography may provide diagnostic clues. Specific therapeutic options to address lung injury after HSCT are limited. Given the paucity of specific therapies to address dysregulated inflammation in the lung, corticosteroids remain the mainstay of therapy, and once initiated, should be tapered slowly. Given the role of tumor necrosis factor (TNF)$\alpha$ in GVHD, etanercept (a soluble TNF$\alpha$-binding protein) has also shown benefit when combined with corticosteroids.[100]

Supportive care for this population of patients includes early initiation of broad-spectrum antimicrobial coverage, including antiviral and antifungal agents.[96,100] Fluid overload among children undergoing HSCT is associated with worse outcomes[101] and should be aggressively managed with diuretic therapy or renal replacement therapy. Early renal replacement therapy can be beneficial, and studies in children have suggested both short-term oxygenation and survival benefits.[102,103] Mechanical ventilation should be initiated early in these patients, but debate continues whether noninvasive or invasive mechanical ventilation should be the initial modality. Prospective trials are lacking, but a recent multicenter retrospective study showed higher mortality among children placed on noninvasive ventilation prior to intubation when compared to those who were intubated without such a trial (odds ratio, 2.1; 95% CI, 1.2–3.6; *P* =.01). Potential explanations for the worse outcome of noninvasive ventilation include it being employed too late to be of benefit or continued too long resulting in a detrimental delayed intubation.[95] Additionally, limitations such as body habitus, skin breakdown, and the presence of mucositis might make noninvasive ventilation an unfeasible modality in these patients. If evidence of pulmonary hypertension is noted, pulmonary vasodilator therapies such as inhaled nitric oxide, sildenafil, and bosentan may be useful.[100]

## Conclusion

Pediatric pulmonologists are commonly consulted to aid in the diagnosis and management of patients admitted to the PICU. A thorough knowledge of the physiology and potential pathology in these complex patients is required to minimize the risk of pulmonary complications and optimize outcomes in this high-risk population.

## 38

# Acute Respiratory Distress Syndrome

*Alik Kornecki MD, Ram N. Singh MBBS, FRCPC*

## Epidemiology

The available epidemiological studies are based on the former North American European Consensus Conference Committee (AECC) definition of acute respiratory distress syndrome (ARDS) from 1994.[1] The incidence of ARDS in children is 3–12.8/100,000 per year,[2,3] which is about 5–8 times less than in adults,[4] and constitutes 2%–10% of all pediatric intensive care unit (PICU) admissions per year.[3,5,6] Approximately 80% of children with mild ARDS will progress to moderate and severe ARDS, and two-thirds of them will require early invasive mechanical ventilation.[7] About 60% of pediatric patients with ARDS are less than 4 years of age and 30%–70% of them suffer from a significant underline disease (e.g., prematurity, genetic or neurologic abnormality, cardiac disease).[2,3,6,8] ARDS affects males and females equally.

## Etiology

A variety of heterogeneous direct *(pulmonary ARDS)* or indirect *(extrapulmonary ARDS)* insults to the lungs may provoke a similar cascade of inflammatory reactions, which leads to ARDS (Box 38.1). In case of *pulmonary* ARDS, the insult is direct in the lungs, and in the case of *extrapulmonary* ARDS, the insult is indirect and the pulmonary lesions are caused by circulating mediators released from extrapulmonary foci into the blood (e.g., sepsis, pancreatitis; Box 38.1). Data provided by Flori and colleagues[8] from a large epidemiological study suggest that pneumonia (bacterial or viral; 35%) and aspiration pneumonia (13%) are the most common causes for direct ARDS, whereas sepsis (13%) is the most common cause for indirect ARDS.

**Box 38.1**

### Common Etiologies for Acute Respiratory Distress Syndrome

#### Pulmonary (Direct)

Pneumonia (viral, bacterial)
  Aspiration pneumonia
  Bronchiolitis
  Near drowning
  Lung contusion
  Toxic inhalation

#### Extrapulmonary (Indirect)

Sepsis
  Nonthoracic trauma
  Transfusion of blood products
  Pancreatitis

## Outcome

The mortality from ARDS among children has decreased significantly from the 65% to 80% reported in the 1980s.[9,10] This reduction can be attributed to the establishment of dedicated pediatric critical care units with improved general management, including the reduction in the administered tidal volumes ($V_T$) during mechanical ventilation.[11] However, in the last two decades the mortality has remained unchanged.[5]

A recent large meta-analysis of 32 studies reported a mortality rate of 33.7% in children with ARDS when defined according to the previous AAEC definition of ARDS.[5] It should be noted that studies performed in western countries reported mortality to be between 4.3%[12] and 30.5%,[13] and studies from Asia reported mortality as high as 61%.[14] The differences in mortality among centers are mainly attributed to patient mix and local resources. In general, mortality is higher among children with underlying immune deficiency, malignancy, status post bone marrow transplantation,[15,16] and with comorbidities (e.g., nonpulmonary organ dysfunction, central nervous system dysfunction)[8]; it is minimal among children with bronchiolitis (<3%). In general, it is perceived that the mortality in children is lower than in adults, and the overall mortality is 27%–45%.[17]

Only one study thus far has reported mortality using the New Berlin definition of ARDS (see below). This European multicenter study reported mortality rates of 13.9% for mild, 11.3% for moderate, and 25% for severe ARDS; however, it was limited to young children aged 1–18 months.[18]

In contrast to adults and premature infants where the quality of life after respiratory failure was studied,[19] the long-term quality of life and lung morbidity among children who recover from ARDS has not been studied. However, we believe that children without underlying lung or cardiac disease recover from a single episode of ARDS without significant mechanical or functional sequelae to the lungs.

## Definition and Diagnosis

ARDS is a form of acute respiratory failure characterized by a diffuse, progressive inflammatory lung disease that was first reported in 1967 by Ashbaugh and colleagues in a cohort of 12 surgical patients.[20] They noted that the patients exhibited “acute onset of tachypnea, hypoxemia and loss of compliance.” Further reports of patients with ARDS altered the acronym to indicate *adult* respiratory distress syndrome, to differentiate it from the respiratory distress syndrome of neonates, even though Ashbaugh's original description included an 11-year-old child. It was not until

1980 that regular reports[9] of ARDS in children established that it was also a pediatric syndrome, and the 1994 North American–European Consensus Conference Committee (NAECC) recommended that the acronym "ARDS" revert to its original meaning (i.e., acute).[1] Most studies in ARDS published until 2014 used the AECC definition of ARDS. The diagnostic criteria have been modified in the Berlin ARDS Conference in 2012 (Table 38.1).[21] The Berlin four-point definition eliminated the group of acute lung injury (ALI) and created three ARDS entities—mild, moderate, and severe—according to the severity of hypoxemia extrapolated from the $PaO_2/FiO_2$ (P/F) ratio. The new definition, like the previous AECC, focuses on adult patients and does not consider different risk factors, epidemiology, and pathophysiology in children. In addition, the adult definition requires arterial blood gases to calculate the P/F ratio, which are not always available in children.

## Table 38.1

### Acute Respiratory Distress Syndrome

| | |
|---|---|
| Timing | Within 1 week of known clinical insult or new or worsening respiratory symptoms |
| Chest imaging | Bilateral opacities—not fully explained by effusions, lobar/lung collapse, or Nodules |
| Origin of edema | Respiratory failure not fully explained by cardiac failure or fluid overload<br>Need objective assessment (e.g., echocardiography) to exclude hydrostatic edema if no risk factor present |
| Oxygenation | — |
| Mild | $PaO_2/FIO_2$ 201–300 mm Hg with PEEP or CPAP ≥ 5 cm $H_2O$[a] |
| Moderate | $PaO_2/FIO_2$ 101–200 Hg with PEEP ≥ 5 cm $H_2O$ |
| Severe | $PaO_2/FIO_2$ ≤ 100 mm Hg with PEEP ≥ 5 cm $H_2O$ |

[a] This may be delivered noninvasively in the mild acute respiratory distress syndrome group.

*CPAP*, Continuous positive airway pressure; *$FIO_2$*, fraction of inspired oxygen.

In 2015 a panel of investigators proposed adaptation of the Berlin definition to children, the pediatric ARDS (PARDS; Table 38.2).[22] The PARDS definition uses the P/F ratio or $SpO_2/FiO_2$ ratio for noninvasive ventilated children and the oxygenation index (OI) or the oxygenation saturation index (OSI), when arterial blood is not available, for ventilated children. The request for bilateral pulmonary infiltrates was eliminated, and a better definition for children with underlying congenital heart disease or chronic lung disease was offered.

**Table 38.2**

**Pediatric Acute Respiratory Distress Syndrome**

| | | | | |
|---|---|---|---|---|
| Age | Exclude patients with perinatal lung disease | | | |
| Timing | Within 7 days of known clinical insult | | | |
| Origin of edema | Respiratory failure not fully explained by cardiac failure or fluid overload | | | |
| Imaging | Chest imaging findings of new infiltrate(s) consistent with acute pulmonary parenchymal disease | | | |
| Oxygenation | Noninvasive MV Invasive MV | | | |
| | CPAP ≥ 5 cm $H_2O$[a] | Mild | Moderate | Severe |
| | P/F ≤ 300 | 4 ≤ OI < 8 | 8 ≤ OI < 16 | OI ≥ 16 |
| | $SpO_2/FiO_2$ ≤ 264[b] | 5 ≤ OSI < 7.5[b] | 7.5 ≤ OSI < 12.3 | OSI ≥ 12.3 |

[a] For nonintubated patients treated with supplemental oxygen on nasal modes of noninvasive ventilation.

[b] Use $PaO_2$ when available; if not available, wean the $FiO_2$ to maintain $SpO_2$ 97% to calculate the OSI or $SpO_2/FiO_2$.

*OI*, Oxygen index; *OSI*, oxygen saturation index.

The classical histological description of ARDS was published in 1976 by Katzenstein and colleagues[23] as diffuse alveolar damage (DAD) associated with the presence of hyaline membranes, interstitial edema, cell necrosis with proliferation, and fibrosis. The validity of the Berlin definition has been tested against lung histopathologic findings in adults undergoing autopsy following clinical ARDS. Among all patients who met clinical criteria for ARDS, DAD was found in only 45%. The proportion of DAD depended on the severity of ARDS, and was more frequent in severe ARDS (58%). Using DAD as the reference standard, the sensitivity and specificity of the diagnosis in adults were 89% (95% confidence interval [CI], 84%–93%) and 63% (95% CI, 59%–67%),[24] respectively. There has been no similar study in children. However, we may expect similar findings, as a comparable study that was performed with the old NAECC definition reported a sensitivity of 81% and a specificity of 71%.[25] The main limitation of these studies was selection bias because they were limited to patients who died; survivors may have had different pathophysiologic findings.

Over the years, various single specific biomarkers or panels of biomarkers, such as surfactant proteins, cytokines, and markers of pulmonary epithelial and endothelial injury, have been investigated for the early diagnosis of ARDS or pending ARDS.[26] However, all these attempts failed because of low sensitivity and specificity. We are still in the search for the "troponin of ARDS."[27]

## Pathophysiology

ARDS arises because of an inflammatory process at the alveolar-capillary interface in the lung. The resultant endothelial and epithelial disruption leads to increased alveolar-capillary permeability and flooding of the alveoli with protein-rich edema fluid. Alveolar gas exchange is impaired and surfactant function is disrupted.[9] In addition, there is uncontrolled activation of coagulation along with suppression of fibrinolysis. Classically, ARDS is described as a progressive clinical condition characterized by four stages, although these are rarely identified in pediatric cases. ARDS is triggered by an acute *direct* injury (e.g., aspiration) or *indirect* lung injury (e.g., sepsis), resulting in the onset of an *acute exudative* phase characterized by pulmonary edema, cytokine release, and activation of neutrophils. The acute exudative stage is associated with increased intrapulmonary shunting, increase in dead space, reduced functional residual capacity (FRC), and a decrease in lung and chest wall compliance.[28] Before the advent of computerized tomography (CT), the acute exudative stage was synonymous with the radiologic finding of bilateral homogenous parenchymal disease; however, pulmonary CT imaging changed our outlook on ARDS, revealing heterogeneity in the extent of regional lung injury, with the coexistence of severely injured (dependent) lung and less injured lung and healthy lung regions. Gattinoni and Pesenti[29] suggested that the lung in ARDS be conceptualized as three functional regions: (1) fully aerated normal (usually nondependent) region(s); (2) poorly aerated injured but recruitable lung; and (3) nonaerated consolidated/atelectatic lung. This group also introduced the term *baby lung* to describe the small volume of normal aerated tissue in the nondependent lung regions of the lung that exhibits normal compliance.

During the acute phase of inflammation, abnormalities in coagulation contribute to the development of small vessel occlusion. In rare cases, pulmonary hypertension, due to vascular obstruction and complicated by right ventricular failure, has been described.[30] The *acute exudative phase* may resolve within hours or days, and some patients do not progress to the subsequent *fibroproliferative early repair phase.* Unfortunately, "repair" may not result in disease resolution in all patients, but may presage the development of *fibrosing alveolitis* characterized by increased alveolar dead space, hypoxia, and reduced lung compliance; progression to this third stage is associated with worse outcome. The fourth stage, the *recovery stage,* occurs within 10–14 days, with gradual improvement in lung compliance and oxygenation. The mechanism of resolution of the acute inflammatory process and fibrosis is not well established, and the rate of recovery is not well characterized; however, a return to normal lung function in those patients without underlying chronic lung disease, is the norm.

Thille and coworkers[31] examined the histopathological changes in a large adult population with clinical ARDS who demonstrated DAD at autopsy examination. The histological findings closely correlated with the duration of evolution of ARDS. The exudative changes were observed in 90% of patients with ARDS of less than 1-week duration, and decreased over time. The occurrence of proliferative changes increased over time and peaked between the second and third week (78%). Fibrosis was noted rarely in the first week (4%) and after 3 weeks it was noted in 61% of patients. Fibrosis occurred more frequent in ARDS of primary pulmonary origin (direct) than that of nonpulmonary origin (indirect).

A somewhat different approach to the pathophysiology of ARDS was proposed by Albert[32] who suggested that ARDS was mainly iatrogenic and not the result of a primary inflammatory process. He proposed that it is a form of ventilation-induced lung injury where the primary problem is atelectasis induced by surfactant abnormalities, and that mechanical ventilation initiates the inflammatory process. If the proposed scenario is correct, at least some instances of ARDS might be prevented by routinely administering a protective strategy of ventilation with sigh breaths, low $V_T$s, and positive end-expiratory pressure (PEEP), avoiding supine positioning, increasing the frequency of repositioning, using prone or semi-prone positioning, and limiting the use of sedation.

## Pulmonary (Direct) Versus Extrapulmonary (Indirect) Acute Lung Injury/Acute Respiratory Distress Syndrome

In the initial description of ARDS, Ashbaugh and colleagues[20] observed that different insults appeared to induce a similar injury to the lung; therefore they postulated that a common mechanism of injury must exist. However, careful observation of the clinical progression and histological lung appearance in patients with ARDS suggested that the pattern of lung injury might depend on the etiology. In 1994, the AECC made a distinction between a direct or pulmonary injury (ARDSp), such as might occur following aspiration pneumonia, and contrasted this pattern with indirect or extrapulmonary (ARDSexp) injury associated with a systemic inflammatory response, such as sepsis or acute pancreatitis (Table 38.3).[1]

### Table 38.3

**Pulmonary Versus Extrapulmonary Acute Respiratory Distress Syndrome**

| | Direct (Pulmonary) | Indirect (Extrapulmonary) |
|---|---|---|
| Morphology | Consolidation | Atelectasis |
| Histology | Epithelial injury, alveolar edema | Endothelial injury, interstitial edema |
| Respiratory mechanics | Reduced lung compliance | Reduced chest wall compliance |
| **RESPONSE TO THERAPY** | | |
| Inhaled NO | ↑$PaO_2$ | →$PaO_2$ |
| Prone position | ↑$PaO_2$ | →$PaO_2$ |
| Surfactant | Possible improved outcome | No effect on outcome |
| Recruitment | →$PaO_2$ | ↑$PaO_2$ |

*NO*, Nitric oxide

Data provided by Flori and colleagues[8] suggest that ARDSp constitutes 60% of pediatric ARDS cases, like the reported incidence of ARDSp in adults (47%–75%). The same authors also reported sepsis as the major cause (13%–21%) of ARDSexp in children. Others have reported a higher incidence of sepsis (70%).[2]

The differences between ARDSp and ARDSexp may be most apparent in the acute exudative phase of the disease. ARDSp is characterized by a primary injury to the alveolar epithelium resulting in intra-alveolar edema, and reduced lung compliance with preservation of the chest wall compliance.[33–35] In ARDSexp, the primary insult is systemic and the major injury is to the capillary endothelium; here the edema is predominantly interstitial, and a greater reduction of compliance occurs in the chest wall. That was recently demonstrated in a study conducted in adults where patients with ARDSp had a significantly higher level of a biomarker of lung epithelial injury (surfactant protein D) and significantly lower levels of biomarkers of endothelial injury (angiopoietin-2, von Willebrand Factor) and inflammatory biomarkers (interleukin [IL]-6 and IL-8) than those with ARDSexp.[36] The gross pathology of the lung in ARDSp suggests predominantly consolidation, and in ARDSexp the striking finding is atelectasis. One of the earliest attempts to characterize ARDS based on the mechanism of injury (i.e., direct vs. indirect), was made by Gattinoni and colleagues,[34] who reported differences in respiratory system mechanics. Subsequently, histologic[35] and morphologic[37] evidence supported the distinction between direct and indirect lung injury. These differences may impact the response to treatment and outcome; indeed, a study in children reported that ARDSexp had a greater mortality than ARDSp.[3] Such differences in functional pathology may explain why in ARDSp there is a greater incidence of refractory hypoxemia and resistance to recruitment maneuvers and prone positioning,[38] but a better response to surfactant administration[39] and inhaled nitric oxide (iNO).[40] In the majority of patients, clinical differentiation between ARDSexp and the ARDSp is simple but of uncertain importance, while in other situations it can be more complex (e.g., trauma complicated by sepsis).

## Severity Score

Blood gas analysis, specifically oxygenation, is regarded as the standard for assessment of severity of ARDS. While the P/F ratio provides the threshold value for the definition of ARDS, the (A–a) $O_2$ difference (difference between “alveolar” vs. arterial $P_{O_2}$) can express the degree of hypoxemia. Both indices should be used with caution because neither incorporates any measure of the respiratory system mechanics nor the *ventilatory* assistance being provided to the patient. In this regard, the OI = [(mean airway pressure × $FiO_2$) × 100]/$PaO_2$ attempts to correct that deficiency. However, even this may mislead if the ventilation strategy employed is not optimized, such as inappropriately high or low airway pressures or $FiO_2$ in the case of an intrapulmonary shunt, which is minimally responsive to altered $FiO_2$ or airway pressure.

Although death in ARDS is usually attributable to multiorgan failure[41] rather than persistent hypoxemia, the severity of oxygenation failure, expressed as the OI,[42] or to a lesser extent as the P/F ratio[43] does correlate with the duration of mechanical ventilation and with mortality in children. In contrast to oxygenation, the ventilation index[44]: [$PaCO_2$ × peak airway pressure × respiratory rate]/1000 has been employed to reflect the difficulty involved in clearing $CO_2$, (i.e., the pulmonary dead space). The magnitude of dead space in the first days of ARDS has been shown to predict outcome in adults[45] and recently in children.[46]

## Genetic Modifiers of Acute Respiratory Distress Syndrome

Other than confirmation that high-pressure, high-volume ventilation is injurious to the lung, the history of ARDS research is replete with interventions that failed to demonstrate clinical benefit.[47] These disappointments often occurred against a background of sound physiologic reasoning and encouraging results from animal studies. It appears that part of the problem has been considering ARDS as a homogeneous disease process. It is already known that only a minority of patients exposed to recognized risk factors develop the ARDS syndrome.

Increasingly, there is recognition that heterogeneity exists in ARDS regarding the development and course of the disease, which is dependent on the interaction of the individual and the inciting event. Consideration of patient-derived factors likely to influence the manifestation of an inflammatory process leads inevitably to scrutiny of the genome. In 2002, Marshall and colleagues[48] were the first investigators to describe a preliminary association between a gene variant and ALI mortality. This group described the increased incidence of a high producer polymorphism of the angiotensin converting enzyme gene in patients with ARDS. Since this report, similar candidate gene studies have revealed a growing number of gene polymorphisms associated with the susceptibility to ALI/ARDS or its clinical course, for example, gene encoding: pulmonary surfactant-associated protein B (SFTPB),[49] IL-6, IL-10, tumor necrosis factor (TNF), angiotensin-converting enzyme,[50] coagulation factor V (F5) and others. It is anticipated that an enhanced knowledge of the role of polymorphisms in ALI/ARDS will permit appropriate grouping of patients for investigation and will facilitate personalized therapy.[51,52]

## Differences Between Children and Adults

Compared to adults, children demonstrate a spectrum of lung and chest wall development as maturation of the lung continues until 8 years of age. Infants and young children have fewer alveoli compared to adults (approximately 20 million alveoli after birth compared to 300 million alveoli by the age of 8 years; the size of each individual alveolus is also smaller in children (150–180 μm vs. 250–300 μm diameter).[53] Together, these two anatomic differences markedly decrease the surface area available for gas exchange. This anatomic variation is prevalent until approximately 8 years of age. The mechanical properties of the lungs of children and infants are also different from those of adults. The infant lung has low inherent elastic recoil, which may protect against lung collapse, so lower PEEP levels may be required to maintain lung recruitment. In contrast, the chest wall of an infant is more compliant, providing less opposition to the natural recoil (deflating tendency). The ribs in infants are more horizontally aligned compared to adults and, in combination with a more compliant chest, it is more difficult to generate negative pressure in the presence of poor lung compliance. Chest wall compliance is inversely related to age, and with pressure preset ventilation, higher chest wall compliance may increase delivered $V_T$ and thereby increase the risk for ventilator-associated lung injury (VALI) in young children.[54] The ratio of lung volume to body weight is greatest in the first 2 years of life, and this suggests that indexing the $V_T$ to body weight may result in a smaller fraction of lung volume being inflated in the young infant compared with the older child. Experimental data indicate that for a given level of inflation, the inflammatory response to either sepsis or high $V_T$, as well as the propensity to structural injury, might be less in infant versus adult lungs. These physiologic differences are important because adult guidelines for lung protective ventilation are predicated on the behavior of a respiratory system that is very different to that of the infant and young child.

# Treatment

Multiple clinical trials for ARDS have been performed in the last three decades, nearly all of them in adults; however, only sporadic trials have shown beneficial effects on mortality. Tonelli and coworkers[47] examined 159 randomized, controlled trials (RCTs) and 26 meta-analyses and found a significant effect on mortality in only two trials for two interventions (low $V_T$, and prone positioning). Moreover, it was difficult to consistently replicate these results in other trials. This does not mean that clinical strategies do not affect the outcome of the patients, but it emphasizes the difficulties faced in studying ARDS.[52] The two main factors that explain this are the heterogeneity in study populations and the lack of standardization of outcome measures.

## Conventional Mechanical Ventilation

Since the introduction of new definitions of ARDS and PARDS, no good epidemiological data are available regarding the requirement for invasive mechanical ventilation among children with PARDS. Based on older studies, we estimate that about 30% of patients with PARDS do not require invasive mechanical ventilation at the onset of the disease, However, almost half of the patients eventually require intubation and mechanical ventilation for disease progression, and almost all children with severe PARDS require invasive mechanical ventilation.[8]

Substantial clinical evidence indicates that the injudicious use of mechanical ventilation can initiate or exacerbate lung injury and contribute to the mortality associated with ALI/ARDS. Studies in animal models have demonstrated that mechanical ventilation may induce lung injury through physical disruption of the alveoli (barotrauma); overdistension of the lung (volutrauma); recruitment and derecruitment of collapsed alveoli (atelectrauma); activation of the inflammatory process (biotrauma); and possibly, toxicity from high levels of oxygen.[55] Such factors may produce histologic damage and increased permeability of the alveolar-capillary interface, which is indistinguishable from the lesions seen in other forms of ALI.

The ventilation factors associated with this iatrogenic lung injury are elevated levels of end-inspiratory airway pressure, large tidal volumes, low levels of end-expiratory airway pressure, and possibly high $FiO_2$. Understanding the roles of elevated levels of inspiratory pressure and $V_T$ from laboratory[56] and clinical[57] studies led to the design of two important outcome studies that compared lower versus higher tidal volumes in patients with ARDS.[58,59] These studies demonstrated a clear association between higher $V_T$ (or inspiratory pressures) and worse outcome. This approach, along with the belief from laboratory and clinical trials[59] that higher levels of PEEP were protective, led to a gradual adoption of the idea that lung protective ventilation, lower tidal volumes, recruitment, and higher levels of PEEP would ensure sufficient gas exchange while minimizing lung injury. Hence, we now employ lower $V_T$, up to 10 mL/kg; lower inflation pressure (<30 cm $H_2O$ plateau pressure); higher PEEP (~5 to 15 cm $H_2O$), and lower $FiO_2$ than two decades ago.[22] It should be noted that the plateau pressure limitations do not consider differences in chest wall compliance between patients. To take this variable into account, one would need to measure the transpulmonary pressure (esophageal pressure). The physiologic goals of mechanical ventilation are not to attempt to achieve normal blood gases values without regard for the $V_T$, $FiO_2$, or inflation pressures delivered to the patient. Mechanical ventilation is employed with consideration of a risk/benefit estimation for each patient. If the achievement of normal pH, $PaCO_2$, and $PaO_2$ levels requires respiratory support strategies that may injure the lungs, then lower pH, $PaO_2$, and higher $PaCO_2$ (permissive hypercapnia) are tolerated. Despite the lack of data regarding the effect of relative hypoxia on human organ systems in general, and on the developing infant brain, the maintenance of $SaO_2$ >90% ($PaO_2$ 60–80 mm Hg) using the lowest oxygen concentration necessary to achieve that result is considered by most pediatric intensivists as an optimal approach. Because the likelihood of lung injury is greater if the airway pressure, $V_T$, and concentration of inspired oxygen are elevated, many clinicians will reduce the target $SaO_2$ (85%–88%) if necessary. Permissive hypercapnia ($PaCO_2$ 60–80 mm Hg) with a pH >7.2 appears to be well tolerated by most children (although it is avoided in the presence of raised intracranial pressure or pulmonary hypertension). The "protective" approach has not been validated in children, and the mechanical ventilation strategies used in children mirror the recommendations of the adult critical care community. This approach is physiologically sound, but given the increasingly recognized heterogeneity of ARDS, it is likely that some subtle disease features peculiar to pediatrics have been ignored.

Few studies of mechanical ventilation have been performed in children, and, as a result, no specific approaches have been proven superior to others. Indeed, most approaches for mechanical ventilation in children have been extrapolated from adult studies. Currently there are no data to support the superiority of one mode of ventilation over another (e.g., pressure control vs. volume control). However, advocates of pressure control ventilation argue that it is more physiologic because of the decelerating flow, and that the $V_T$ generated during each breath better reflects dynamic lung characteristics. Interestingly, two surveys reported that clinicians demonstrate a preference for pressure targeted ventilation and pressure regulated volume control (PRVC) ventilation when treating children.[6,60]

## Other Modalities of Ventilation

### Noninvasive Ventilation

To limit complications associated with endotracheal intubation, noninvasive ventilation (NIV) has been gaining increasing attention in the last few years and it is the focus of several studies.[61] NIV may be administered with positive or negative pressure ventilation and, more recently, through high-flow nasal cannula (HFNC). Since no data are available on the role of negative pressure ventilation in PARDS; we focus here on the use of noninvasive positive pressure ventilation (NIPPV) and HFNC.[62] The role of NIPPV in the pediatric population is not fully characterized and only one RCT in children with acute respiratory failure has been published.[63] In that study of 50 children with acute hypoxemic respiratory failure, NIPPV was compared with standard care. The authors found that the frequency of intubation was significantly lower in the group that received NIPPV (28% vs. 60%). A trial of NIPPV may be attempted in any child with early respiratory failure and mild to moderate PARDS; especially in children with immunodeficiency who are at greater risk of complications from invasive mechanical ventilation. However, one should not persist with its use if there is no clinical benefit within a short time. It appears that patients who are hemodynamically unstable, have a greater severity of illness, or have moderate to severe PARDS are less likely to benefit from NIPPV.[64] Almost any ventilator may be used to provide NIPPV in volume, pressure modes, or a bilevel controlled or continuous positive pressure (CPAP) device can be used. Recently it was reported that the use of neurally adjusted ventilator assist (NAVA) mode[65] resulted in a dramatic reduction in patient-ventilator asynchronies and in trigger delay compared with the pressure control mode of ventilation in infants with severe bronchiolitis. NIPPV may be administered using facial, oronasal or nasal masks. Compared with oronasal masks, nasal masks are better tolerated in younger children. However, nasal interfaces are associated with significant more air leaks and patient-ventilator asynchrony. In contrast, the full facemask is less tolerated and increases the risk of aspiration. In addition, both interfaces do not permit pressures greater than 20 cm $H_2O$ on an ongoing basis.

In the last 5–10 years, HFNC replaced the traditional nasal cannulas for oxygen administration and the “conventional” NIPPV. The old nasal cannulas used flows of 0.5–4 L/min of dry unheated gas. In contrast, HFNC consists of an air–oxygen blender, which delivers heated humidified gas through nasal prongs with flows as high as 60 L/min. It has been proposed as an alternative to CPAP and “conventional” NIPPV.[66,67]

Most of the studies on the use of HFNC in infant and children are small observational studies, which have shown beneficial effects in bronchiolitis.[68,69] Other studies show that the system is well tolerated, safe,[70] and reduces the breathing effort.[71] However, the potential benefit in reducing the rate of intubation in PARDS has not been studied. In a recent RCT trial in adults with acute hypoxemic respiratory failure, treatment with high-flow oxygen, standard oxygen administration, or conventional NIV did not result in significantly different intubation rates.[72]

The mechanism of action of HFNC is not well understood and includes (1) the washout of nasopharyngeal dead space, resulting in increased $FiO_2$ and reduced carbon dioxide in the dead space; (2) the reduction of inspiratory resistance; and (3) the reduction of the metabolic cost of gas conditioning by providing air with 100% relative humidity and providing an end-expiratory positive pressure.[73]

## High-Frequency Oscillatory Ventilation

A variety of high-frequency ventilation devices are available for clinical use; however, high-frequency oscillatory ventilation (HFOV) has achieved the greatest acceptance in neonatal, pediatric, and adult critical care practice. According to several studies, between 5% and 52% of children with acute respiratory failure are ventilated using HFOV at some stage during their disease.[3,6,74] HFOV achieves effective gas exchange while avoiding high peak airway pressures and the inflation–deflation cycles characteristic of conventional ventilation. Lung volume (and hence oxygenation) is maintained by the application of a high continuous mean airway pressure. $CO_2$ removal is achieved despite small tidal volumes (2–4 mL/kg) by imposing a breath frequency of 300–900 (5–15 Hz) per minute, resulting in large minute volumes. Therefore HFOV involves the application of the open lung strategy accompanied by small swings in pressure and volume in the distal airways and alveoli.[75] Hence, the cyclical application of high distending airway pressures (barotrauma) and the associated cyclical delivery of large tidal volumes (volutrauma) are avoided. In animal models of ALI/ARDS, HFOV has demonstrated comparable or superior gas exchange when compared with conventional ventilation while producing less lung injury.[76] HFOV would appear to represent an optimal lung protective ventilatory device; however, with the progress in protective conventional mechanical ventilation (CMV), it is being deployed only when CMV fails. Although there are no established criteria to define CMV failure, in general HFOV is considered when, despite a plateau pressures of 30–32 cm $H_2O$ and $FiO_2 > 0.6$, there is inadequate oxygenation and/or significant hypercapnia. Two studies comparing HFOV to CMV in children with respiratory failure were published recently. The first study was a secondary analysis of a sedation study, compared the early (24–48 hours) application of HFOV in 181 children to 883 children that received CMV and/or late application of HFOV.[77] The early application of HFOV was associated with a longer duration of mechanical ventilation, but the mortality was similar in the two groups. The second study was a retrospective study that included 1764 patients in 98 hospitals. It showed that early or late application of HFOV was associated with increased mortality (17.3% vs. 8.4%), increased duration of mechanical ventilation, and increased length of stay in the intensive care unit (ICU).[78] The results of these studies are similar to two recently published RCTs in adults, where the early application of HFOV in unselected etiologies of ARDS showed no effect,[79] or an increase in mortality (47% vs. 35%).[80] A different study in adults, in a selected group of patients with severe pulmonary ARDS, hypercapnia, and acidosis, showed a rapid and persistent reduction in $CO_2$ without adverse effect.[81]

This supports the argument that a trial of a therapeutic intervention in a heterogeneous disease like ARDS should be examined only in selected, well-defined groups of patients.

## Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is a ventilator modality characterized by cyclical alternation between two levels (high and low) of positive airway pressure, while permitting spontaneous breathing activity at both levels of pressure support. Typically, 80%–95% of the ventilatory cycle is accounted for by the higher pressure ($P_{high}$, usually 15–30 cm $H_2O$) and is only briefly interrupted by drops to a lower level of airway pressure ($P_{low}$, usually 0–15 cm $H_2O$). The duration of both the $P_{high}$ and $P_{low}$ periods are time cycled and continue even when spontaneous breathing is not detected. In such a case, APRV will resemble inverse (inspiratory: expiratory) ratio pressure-control ventilation with a very long inspiratory time. APRV, facilitates an open lung ventilatory approach, avoids cyclical recruitment and derecruitment of alveolar units, permits homogenous gas distribution during inspiration, minimizes overdistension of healthy lung (volutrauma), and reduces the risk of low-volume lung injury (atelectrauma).[82] There have been few studies of the role of APRV in pediatric and adult ARDS. It has been shown that in children with mild to moderate lung disease, APRV provides good efficacy in ventilation and oxygenation compared with conventional ventilation with significantly lower peak and plateau airway pressures.[47] Despite the potential benefits of APRV, it is not a common modality of ventilation in children. A recent survey of the daily practice of mechanical ventilation among 18 medical centers in Italy reported that less than 4% used APRV.[83]

## Neurally Adjusted Ventilatory Assist

Patient-ventilator dyssynchrony is a major issue in the delivery of mechanical ventilation to patients capable of spontaneous breathing. More than 25% of adult ventilated patients exhibit dyssynchrony.[84] Key considerations in patient-ventilator synchrony include signaling of the onset of the patient's inspiratory effort, the pressure/flow profile of gas delivery during the breath, and mechanisms to signal termination of the patient's inspiratory effort. NAVA is a relatively recent innovation to improve such synchrony in invasive[85,86] and, more recently, in noninvasive ventilation.[87] The NAVA system utilizes the electrical activity of the diaphragmatic (right crural) muscle to signal the initiation of patient inspiratory effort. The signal is detected using electrodes embedded in the distal end of a gastric tube that is positioned astride the esophageal hiatus of the diaphragm. Because muscle electrical activity is proportional to the strength of the phrenic signal (which itself reflects the respiratory demands of the patient), the NAVA system offers both improved triggering and variable ventilatory support proportionate to the patient's respiratory demands. This is an improvement over circuit pressure or gas flow triggering systems and the use of a fixed amount of ventilatory support with each breath. There are only few reports of NAVA use in either adults or children.[86,88] It has been demonstrated that NAVA prevents excessive lung distension, efficiently unloads respiratory muscles, and improves, but does not completely abolish, patient-ventilator dyssynchrony. The penetration of this modality of ventilation in pediatric critical care units is unknown; however, we speculate that it is very low, as most surveys do not mention it.[6]

# Adjuvants to Mechanical Ventilation

Prone positioning, surfactant, and nitric oxide administration have all been employed as adjuvant therapies in ventilated patients with ALI/ARDS. To date, none of these interventions has demonstrated an ability to improve patient outcome except for prone positioning in adults when employed as a routine part of care.[47]

## Corticosteroids

The use of corticosteroids for the treatment of ARDS was suggested by Ashbaugh in 1967.[20] Almost 50 years and several clinical trials later, it is still the subject of debate.[89,90] ARDS is characterized by inflammation that may resolve within a short period; alternatively, it may progress to the unresolving inflammatory (i.e., fibroproliferative) stage. The antiinflammatory properties of corticosteroids and the potential inhibition of both fibroblast proliferation and collagen deposition make corticosteroids an attractive option.

The use of corticosteroids has been examined (in adult patients) in different disease stages, including prophylactically (before development of ALI/ARDS),[91] during the early stages of disease (<7 days),[92] and in later stages of the disease (>7 or 14 days).[93] Corticosteroids have been used for different durations and at different doses. Early studies focused on the prevention of ARDS after events that are known to potentially lead to ARDS (e.g., sepsis). High doses (≥30 mg/kg/day) of corticosteroids for a short period of time (≤24 hours) either had no impact on mortality[91] or, in one case, increased mortality.[94] A relatively recent study of early low-dose corticosteroids (1 mg/kg/day) for 25 days demonstrated a treatment benefit with improvements in lung injury score, days of ventilation, and mortality.[92] However, methodological issues provoked significant controversy. Several studies that examined the role of corticosteroids late in the course of the disease (>7 days) reported contradictory results,[93,95] and there is some evidence that steroids introduced after 2 weeks of illness may result in increased mortality.[95] An examination of adult patients with sepsis-induced ARDS who were nonresponders to adrenocorticotropic hormone (ACTH) stimulation testing demonstrated improved lung function and decreased mortality with low-dose steroid use in early disease. This study underscores the importance of selecting groups likely to benefit from steroids when studying their potential use in ARDS.[96] A recent analysis of patient data from four randomized trials demonstrated that early and prolonged glucocorticoid treatment accelerated resolution of ARDS and decreased mortality without increasing the risk of infection.[97] In children, only a few case series are available. Recently, it was reported in an observational single study that corticosteroid exposure (>24 h) in children with PARDS is associated with fewer ventilation-free days after adjustment for key potential confounders, including severity of illness, OI, immunocompromised status, and number of organ failures.[98]

In summary, current evidence from clinical trials does not support the use of corticosteroids in any phase of ARDS in adults. Further investigations are required to address the paucity of data in children and to specifically identify potential responders among the population of ARDS patients.

Clinicians should remain vigilant for steroid-responsive diseases, such as acute eosinophilic pneumonia, hypersensitivity pneumonitis, diffuse alveolar hemorrhage from vasculitis, nonspecific interstitial pneumonitis and others, which may present as PARDS.

## Prone Positioning

Prone positioning is safe and has been reported to produce a rapid and sustained improvement in arterial oxygenation in 90% of children with PARDS.[99] This response rate was superior to that reported in adults (60%). However, the improvement in oxygenation did not translate into a reduction in days of ventilation or patient mortality in children. Prone positioning is best reserved for patients with persistent refractory hypoxemia when acceptable oxygenation cannot be achieved within the parameters of a lung protective ventilatory strategy. However, where it does not improve oxygenation, it should be discontinued. A multicenter comprehensive study reported that 17.6% of children with ALI/ARDS receive prone positioning as part of their management at some time during their disease.[6]

## Inhaled Nitric Oxide

Nitric oxide is a potent short-acting selective pulmonary vasodilator. It has been shown to result in short-term improvements in oxygenation in some patients with ARDS/ALI, but it has no substantial impact on the duration of ventilator support or mortality when used as a routine part of care. Currently, only a minority (12%) of children with ALI receive iNO during the disease.[6] The routine use of iNO is not recommended, but it may be considered in a selected group of patients with pulmonary hypertension or significant right ventricular dysfunction.[22] In addition, it may be considered for patients with refractory hypoxemia, with $FiO_2$ >0.6, and in whom a trial of iNO demonstrated benefit. Where inhaled iNO is being used, some recommend that a daily trial be conducted to ensure that the minimal effective dose is being used, because it has been shown that the iNO dose can be reduced during the course of the disease.[100]

A recent RCT in adults with moderate to severe ARDS demonstrated significantly better pulmonary function tests 6 months after treatment among adult patients treated with a low dose of iNO (5 PPM) compared to similar patients who received placebo.[101] The potential long-term protective role of iNO in patients with ARDS or PARDS should be explored.

## Surfactant

The potential role of surfactant dysfunction in the pathogenesis of ARDS was suggested by Ashbaugh.[1] The concept of surfactant administration to patients with ARDS is very attractive, especially when seen in the context of its benefits in infant respiratory distress. However, at this stage, routine surfactant administration is not recommended. Comparison of results among studies is complicated by the differences in surfactant preparations and delivery methods. Walmrath and colleagues[102] reported improvement in oxygenation when a high dose of bovine surfactant was administered to patients with ARDS and sepsis. Spragg and colleagues[103] reported transient improvement in oxygenation when recombinant surfactant was administered to adult patients with ARDS in a phase III trial; in a post hoc analysis, they also reported a potential improvement in mortality in ARDSp but not in "extrapulmonary" ARDSexp. In children, a relatively small RCT reported a reduction in mortality (19% in the surfactant vs. 36% in the placebo group) following administration of natural calf surfactant[104]; however, there was an unequal distribution of immunocompromised patients among the groups, and controlling for immunocompromised state in multifactorial analysis rendered no difference in mortality between the two treatment groups. Furthermore, there was no effect on ventilator-free days or length of hospitalization. In summary, the routine administration of surfactant in children with PARDS is not recommended. Whether the lack of effect on outcome is a matter of surfactant preparation, patient selection, or method of administration is unclear. However, the transient improvement in oxygenation associated with surfactant administration is tempting, and a survey from 59 centers indicated that more than 50% of intensivists administer surfactant to selected patients with PARDS.[6]

## Neuromuscular Blocking Agents

In contrast to paralyzed patients, where it has been shown that most of the tidal breath is delivered directly to the nondependent regions,[105] during spontaneous ventilation, tidal breathing is directed to the dependent better perfused regions,[106] thus reducing dead space and shunt. Therefore until recently, maintaining spontaneous breathing has been recommended in ventilated patients with ARDS. A relatively recent RCT in adults with severe ARDS reported that continuous neuromuscular blockade (NMB; with cisatracurium besylate) during the first 48 hours of ventilation in severe ARDS significantly reduced mortality.[107] Mortality at 90 days in the NMB group was 32% compared with 41% in the controls. This followed earlier mechanistic studies demonstrating that administration of NMB for the first 48 hours of ventilation improved oxygenation and lowered inflammatory markers (IL-8 and IL-6) in the lung bronchoalveolar lavage [BAL]) and serum of patients with ALI/ARDS.[108]

The mechanism of benefit from NMB is speculative. Paralysis of ventilated patients may facilitate protective ventilation through optimization of patient/ventilator synchronization through more accurate adjustment of $V_T$, or by reduction in inspiratory plateau pressure (because of the reduction in chest wall compliance). Moreover, the use of NMB may reduce the oxygen consumption, which, in turn, will reduce cardiac output and lung perfusion, and may reduce lung injury.

A recent study in 23 children with respiratory failure reported that short-term NMB resulted in a significantly improved OI in all patients while the distribution of $V_T$ and regional lung filling characteristics were unaffected.[109] No data are available regarding the prevalence of use of neuromuscular blocking agents among children. Until more pediatric data are available, the use of NMB should be reserved for patients in whom sedation alone is inadequate to achieve effective mechanical ventilation.

## Beta-Adrenergic Agonists

Alveolar edema in ALI/ARDS is mainly due to increased permeability and, to a lesser extent, to increased capillary hydrostatic pressure. The resolution of alveolar edema is critical to recovery from lung injury. $\beta_2$ agonists may reduce alveolar edema by several mechanisms. Alveolar fluid clearance is enhanced through upregulation of $Na^+$ transport in the alveolar epithelial cells by $\beta_2$ agonists. In addition, pulmonary vasodilatation and the resulting reduction of pulmonary vascular pressure results in lowered capillary hydrostatic pressures, and $\beta_2$ agonists may independently decrease endothelial permeability.

An RCT in a small number (40) of adult patients[110] demonstrated that intravenous (IV) salbutamol (albuterol) reduced the extravascular lung water content and, perhaps as a result, lessened the inspiratory airway pressures required for ventilation. An observational review of children with ARDS suggested that inhaled bronchodilators were associated with a lower mortality.[8] Whether inhaled or IV treatment may affect outcome in patients with ARDS is still to be established in an RCT. However, the current evidence discourages the use of $\beta_2$ agonists in ALI/ARDS patients.[111]

## Extracorporeal Life Support in Pediatric Acute Respiratory Distress Syndrome

Although pediatric extracorporeal life support (ECLS) is predominantly employed for cardiovascular support,[69] it may have an important role in some pulmonary cases, especially where ARDS results from trauma. For pure respiratory failure in the absence of cardiovascular compromise, venovenous cannulation is appropriate. This provides oxygenated blood into the right ventricle, but does not augment cardiac output. In contrast, venoarterial cannulation, providing oxygenated blood into the aorta under pressure, effectively augments the cardiac output while concomitantly increasing systemic oxygenation.

The survival rate (60%) for ECLS in ARDS has not substantially changed in the last 15 years,[112] in contrast to the improved outcomes associated with conventional management. Because of the improvement in outcomes associated with conventional ventilation, and because ECLS is used only when conventional ventilation has "failed," the efficacy of ECLS may be progressively underestimated because of "referral bias" of progressively more futile cases. Currently, there are no nationally agreed criteria for ECLS in PARDS, and its use is mainly decided by the center. The two potential major criteria for severity of PARDS and ECLS criteria are OI and the P/F ratio. The consensus at this stage is that ECLS may be considered in severe PARDS with persistent inadequate gas exchange (mainly hypoxia), and where the cause of respiratory failure is potentially reversible.

### Tracheostomy

Ventilation via a tracheostomy tube has many purported benefits in facilitating weaning from mechanical ventilation: it improves patient comfort, reduces the work of breathing, facilitates bronchopulmonary toilet, reduces the incidence of pneumonia, and improves airway security. In addition, it may reduce the length of stay in the hospital or ICU, and reduce hospital costs, but most importantly, a tracheostomy facilitates patient weaning from mechanical ventilation and lowers patient mortality.[113] For these reasons, tracheostomy has become almost routine in adult critical care, with around 8%–25% of all ventilated adult patients undergoing the procedure during their stay.[114] Considering tracheostomy in an adult patient who is expected to require prolonged ventilation (>14 days) is recommended.[115] In contrast, there is no literature describing the preemptive use of tracheostomy in children in whom prolonged ventilation is anticipated. The prevalence of tracheostomy among children requiring prolonged mechanical ventilation was reported in a limited number of studies and varied from less than 1.5%–2%.[116–118] The differences in prevalence between adult and children may be explained by the faster resolution of ARDS in children compared with adults, as well as the introduction of a percutaneous dilatational tracheostomy technique, which is performed at the bedside in adults.[119] However, this technique is not suitable for children younger than 12 years of age, and tracheostomy is perceived as an aggressive procedure with high complication rates in children. A recently published study revealed a significant risk for morbidity and mortality among children under the age of 2 years undergoing tracheostomy.[120]

## Summary/Conclusion

ARDS is a form of acute respiratory failure characterized by a diffuse and progressive inflammatory lung disease. It is caused by a variety of heterogeneous pulmonary or extrapulmonary insults to the lungs that provoke a cascade of inflammatory reactions leading to an increase in the permeability of the alveolar-capillary barrier, which, in turn, leads to alveolar edema and surfactant deactivation. ARDS presents with pulmonary infiltrates on chest radiographs, moderate to severe hypoxemia, ventilation abnormality, reduction in the respiratory system compliance (chest wall, lungs or both) and increased work of breathing in the absence of evidence for cardiogenic pulmonary edema. The diagnostic criteria have evolved from the older European and American consensus definition to the novel Berlin definition,[21] which is exclusively based on clinical criteria with some minor changes in children (PARDS).[22] There is no specific treatment for ARDS except for symptomatic support and treatment of the underline causes (e.g., sepsis, pneumonia). Mechanical ventilation, invasive or noninvasive, is provided to reduce the work of breathing until resolution of the disease has occurred. With the improvements in mechanical ventilation and lung protection that have been developed in the last two decades, the outcome has improved and is generally good with a mortality rate of 7%–35%, unless the patient has underlying chronic lung disease or is immunocompromised. The goals of mechanical ventilation are not to attempt to achieve normal blood gases values without regard to the $V_T$, $FiO_2$, or inflation pressures delivered to the patient, but it is employed with regard to a risk/benefit estimation performed for each patient.

# Pulmonary Disease Associated With Congenital Heart Disease

*Wilson King MD, Kenneth O. Schowengerdt Jr., MD*

## Introduction

Both acute and chronic pulmonary disease may be present in the setting of various forms of congenital heart disease. Postoperative atelectasis, pulmonary edema, or pleural effusions are commonly seen after cardiac surgery, particularly when cardiopulmonary bypass is required. Atelectasis with resultant ventilation-perfusion mismatch, pulmonary edema, and pulmonary hypertension (not specifically in association with congenital heart disease) are discussed elsewhere within the text, and this chapter will focus on more specific pulmonary conditions that may be encountered in association with congenital heart disease.

## Airway Compression Due to Vascular

# Rings and Slings

## Background

Pulmonary vascular rings are congenital vascular conditions in which the trachea and esophagus are encircled by vascular structures, as first reported and surgically repaired by Dr. Robert Gross in 1945.[1] Vascular rings are considered rare and thought to represent only approximately 1% of all congenital heart conditions.

Vascular rings develop secondary to abnormalities of embryological vascular development as described below.[2] During normal fetal development, the aortic sac gives rise to six paired vascular branchial arches that connect to the right and left dorsal aortae (Fig. 39.1).[3] The dorsal aortae give rise to intersegmental arteries at each segmental level that connect to the vertebral arteries. Part of the aortic sac becomes the ascending aorta, and the distal portions of the right and left dorsal aorta fuse to become the descending aorta. The proximal left-sided dorsal aorta remains patent and becomes the proximal descending aorta, and the proximal right-sided dorsal aorta regresses. The third, fourth, and sixth branchial arches contribute primarily to the development of the aortic arch and proximal head and neck vessels. The third branchial arches become the common carotid arteries. The right fourth branchial arch becomes the proximal right subclavian artery, and the left fourth branchial arch becomes the transverse aortic arch. The seventh right intersegmental artery becomes the distal right subclavian artery, and the seventh left intersegmental artery becomes the left subclavian artery. The proximal right sixth branchial arch becomes the right pulmonary artery, and the distal right sixth branchial arch regresses. The proximal left sixth branchial arch becomes the left pulmonary artery, and the distal left sixth branchial arch becomes the patent ductus arteriosus that eventually becomes the ligamentum arteriosum upon closure.

The most common type of vascular ring is the double aortic arch (Figs. 39.2 and 39.3). The ascending aorta gives rise to left-sided and right-sided aortic arches with symmetrical takeoff of carotid and subclavian arteries before connecting with the proximal descending aorta. This occurs if the right-sided dorsal aorta and right fourth branchial arch, which normally regress, persist. The normal left-sided dorsal aorta and left fourth branchial arch also persist. In this situation, the trachea and esophagus are completely encircled by left and right aortic arches.

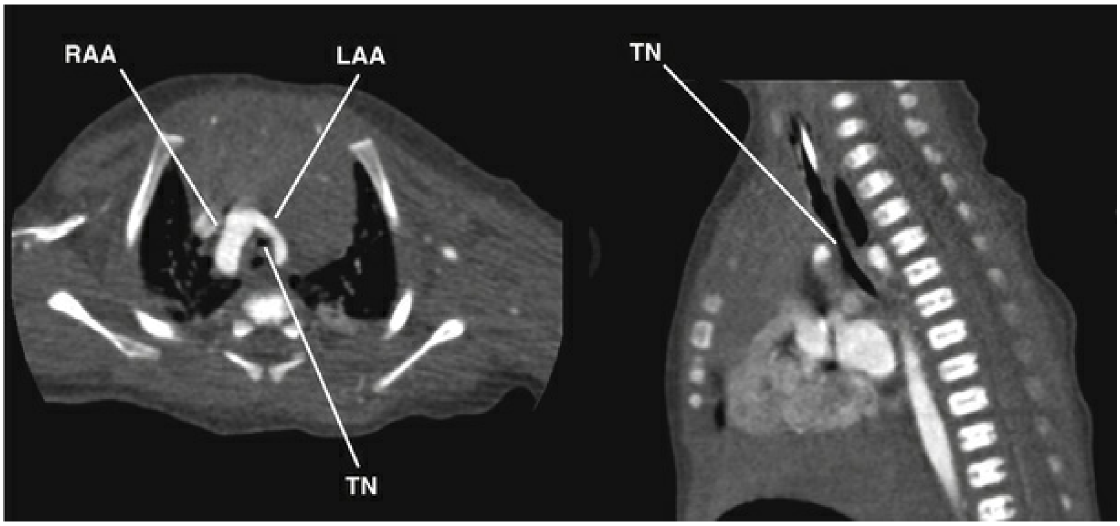

**FIG. 39.2** Double aortic arch with axial and coronal oblique planes from computed tomography angiography. Note right dominant aortic arch and discrete tracheal narrowing at the level of the vascular ring. *LAA,* Left aortic arch; *RAA,* right aortic arch; *TN,* tracheal narrowing.

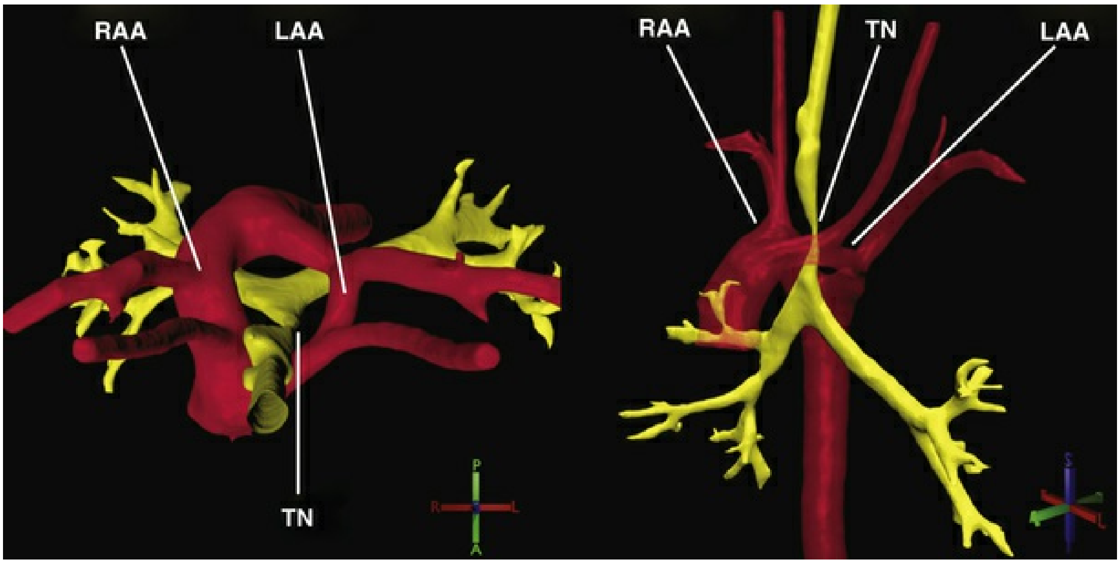

**FIG. 39.3** Double aortic arch reconstruction from axial and sagittal oblique projections. Note discrete tracheal stenosis adjacent to the right dominant arch. *LAA,* Left aortic arch; *RAA,* right aortic arch; *TN,* tracheal narrowing.

The second most common type of vascular ring is when there is a right aortic arch in association with an aberrant left subclavian artery (Figs. 39.4 and 39.5). The head and neck vessel branching order is as follows: left carotid artery, right carotid artery, right subclavian artery, and aberrant left subclavian artery that takes a retroesophageal course. This occurs when the right-sided dorsal aorta and right fourth branchial arch persist, the left-sided dorsal aorta and left fourth branchial arch regress, but the left dorsal aorta remains patent. The trachea and esophagus are completely encircled by the right aortic arch and left ligamentum arteriosum which spans the proximal left pulmonary artery and the distal transverse aortic arch near the insertion of the left subclavian artery. Dilation of the proximal left subclavian artery or Kommerell diverticulum is often seen in the setting of a right aortic arch with an aberrant left subclavian artery. This can also cause tracheal and esophageal compression. In addition to double aortic arch and right aortic arch with aberrant left subclavian artery, there are additional complete vascular and incomplete vascular rings such as circumflex aorta, persistent fifth aortic arch, and cervical aortic arch. However, these are less common.

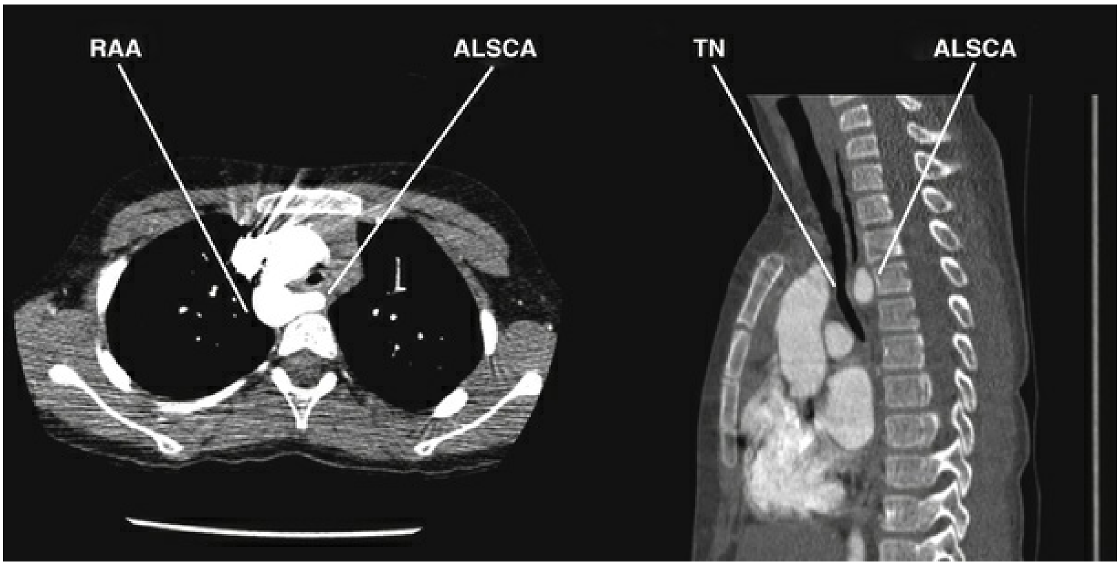

**FIG. 39.4** Right aortic arch with retroesophageal aberrant left subclavian artery with axial and sagittal planes from computed tomography angiography. Note tracheal narrowing adjacent to proximal aberrant subclavian artery. *ALSCA,* Aberrant left subclavian artery; *RAA,* right aortic arch; *TN,* tracheal narrowing.

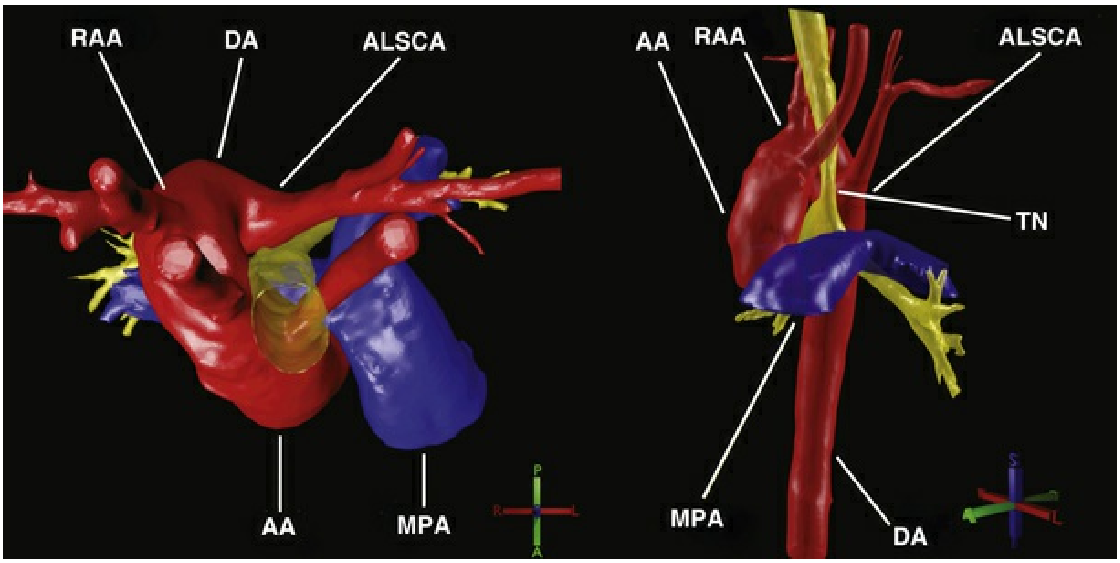

**FIG. 39.5** Right aortic arch with aberrant left subclavian artery reconstruction with axial and sagittal oblique projections from computed tomography angiography. The ligamentum arteriosum connects the main pulmonary artery to the aorta at the takeoff of the aberrant left subclavian artery. *AA,* Ascending aorta; *ALSCA,* aberrant left subclavian artery; *DA,* descending aorta; *MPA,* main pulmonary artery; *RAA,* right transverse aortic arch; *TN,* tracheal narrowing.

Although not a true vascular ring, a pulmonary artery sling is a condition when the left pulmonary artery connects directly to the right pulmonary artery instead of connecting to the pulmonary trunk (Figs. 39.6 and 39.7). The left pulmonary artery then courses posterior to the trachea and anterior to the esophagus causing tracheal compression. Pulmonary slings can be associated with primary tracheal stenosis with extended segments of complete tracheal rings.[4,5]

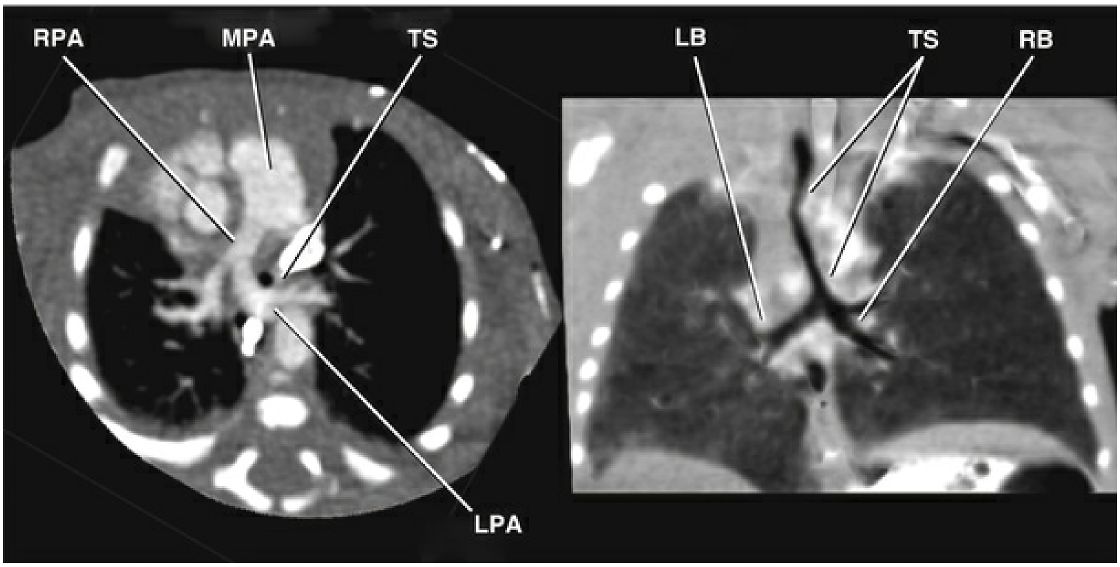

**FIG. 39.6** Pulmonary sling in a neonate with axial oblique and coronal oblique planes from computed tomography angiography. Note that the right pulmonary artery gives rise to the left pulmonary artery, the long segment tracheal stenosis, cardiac dextroposition, and thoracic situs inversus. *LB,* Left bronchus; *LPA,* left pulmonary artery; *MPA,* main pulmonary artery; *RB,* right bronchus; *RPA,* right pulmonary artery; *TS,* long segment tracheal stenosis.

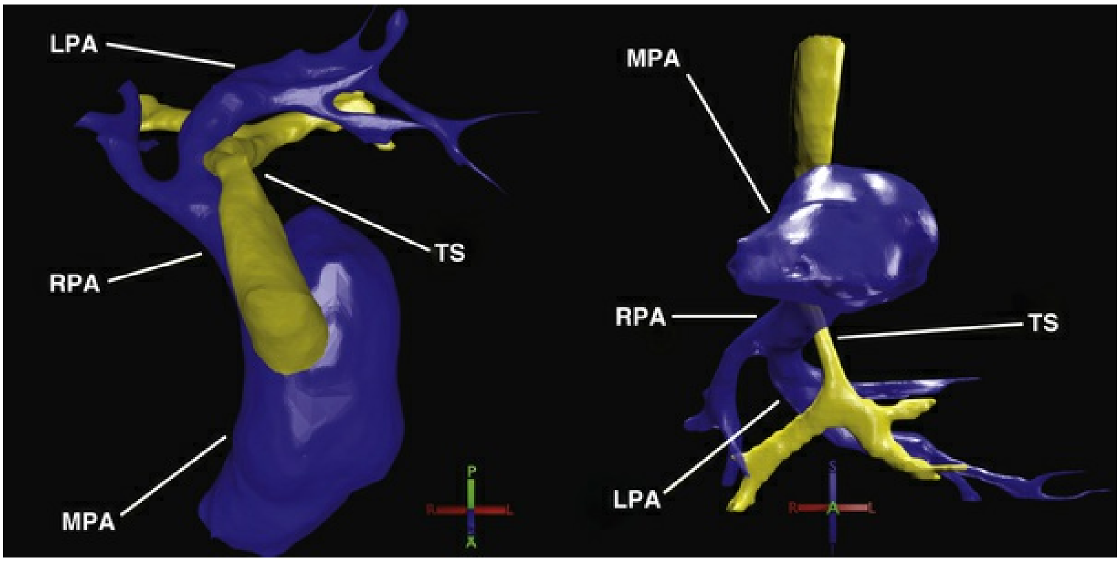

**FIG. 39.7** Pulmonary sling reconstruction from a axial and coronal oblique projections. Note that the left pulmonary artery courses posterior to the trachea. *LPA,* Left pulmonary artery, *MPA,* main pulmonary artery, *RPA,* right pulmonary artery, *TS,* long segment

tracheal stenosis.

Tetralogy of Fallot with absent pulmonary valve is a particular variation of this condition that can be associated with significant respiratory compromise (Fig. 39.8). In addition to presence of a ventricular septal defect, overriding aorta, pulmonary stenosis, and right ventricular hypertrophy, a thick ring of tissue at the pulmonary valve annulus in place of a pulmonary valve results in significant pulmonary stenosis and regurgitation.[6,7] Massive dilation of the main and branch pulmonary arteries can result in significant compression of the trachea and bronchi.

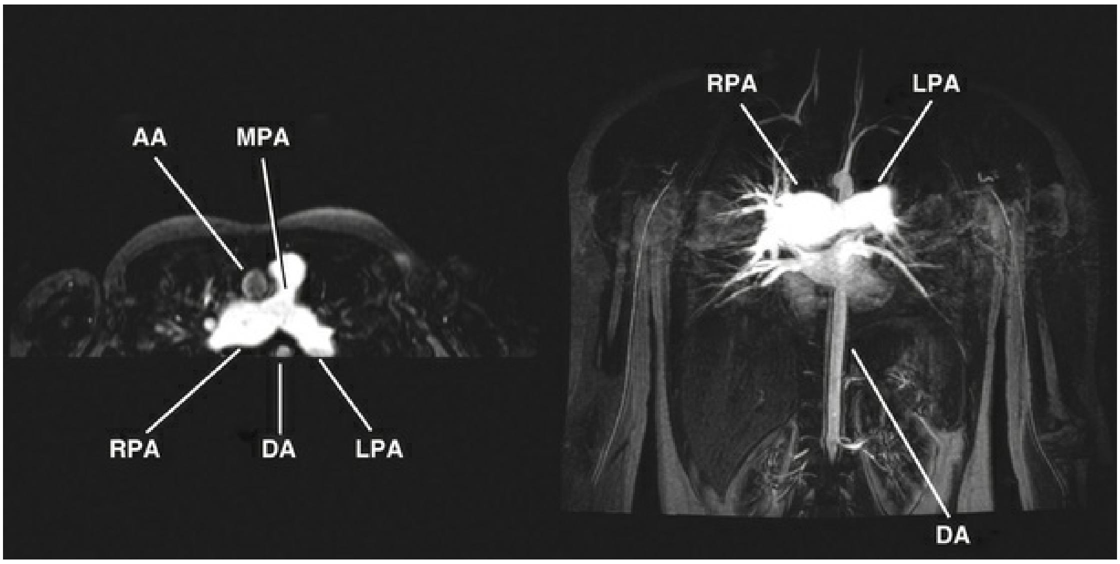

**FIG. 39.8** Tetralogy of Fallot absent pulmonary valve syndrome from magnetic resonance angiography from an axial reformat and coronal reformat with maximal intensity projection showing extremely dilated left and right pulmonary arteries in contrast to normal-sized ascending aorta and descending aorta. *AA,* Ascending aorta, *DA,* descending aorta, *LPA,* left pulmonary artery, *MPA,* main pulmonary artery, *RPA,* right pulmonary artery.

## Clinical Presentation

Pulmonary vascular rings typically present with respiratory or gastrointestinal symptoms.[4,9] Respiratory signs and symptoms may include noisy breathing, barking cough, wheezing, frequent upper respiratory infections, apneic episodes, or intermittent cyanosis. Gastrointestinal symptoms typically do not present until patients begin eating solid foods. The symptoms may include a sensation of food being stuck in the throat, slow eating, or hyperextension during feedings. Typically, patients with double aortic arches tend to present earlier in life with more profound symptoms than patients with right aortic arch and an aberrant left subclavian artery. Backer et al. reported a series of patients with double aortic arch typically presenting before one month of age and those with right aortic arch and aberrant left subclavian artery generally between 1 and 6 months of age.[4] Patients having a pulmonary artery sling may also have associated "ring-sling" complex in which the trachea is not only compressed by the posterior left pulmonary artery, but the presence of complete tracheal rings that also create further narrowing of the airway. The ring-sling complex is associated with significant respiratory symptoms with high morbidity and mortality. Patients with tetralogy of Fallot with absent pulmonary valve syndrome present with significant respiratory distress during the neonatal period in slightly less than half of all cases. They are often cyanotic initially, although this seems to improve with time.

## Diagnosis

Chest x-ray can often suggest the diagnosis of a vascular ring from the position of the aortic knob, apparent tracheal narrowing, and/or unilateral hyperinflation of the lung. Barium swallow has also been used to diagnose vascular rings based on patterns of esophageal compression. Echocardiography may be used to diagnose a vascular ring by delineating the course of the aorta and proximal and neck vessels. A secondary imaging modality is usually required since the airway cannot be evaluated by ultrasound. Echocardiography is nonetheless recommended in patients diagnosed with vascular rings as many have associated congenital heart abnormalities.

In the current era, pulmonary vascular rings are now typically evaluated by tomographic imaging, either computed tomography

(CT) with contrast or magnetic resonance imaging (MRI) with or without contrast. Computed tomography allows the airway and vascular anatomy to be evaluated rapidly, oftentimes without the need for sedation. MRI provides excellent evaluation of the blood vessels with the advantage of avoiding ionizing radiation. The airway can be evaluated using spin echo techniques. However, longer acquisition times often require sedation in younger patients.

Bronchoscopy is an important technique in evaluating some patients with vascular rings. Direct observation of the airway can be very useful in determining the both the degree and mechanism of airway obstruction.

## Treatment

Patients with a vascular ring who are symptomatic are treated surgically. In the case of double aortic arch, the vascular ring is typically relieved by resection of the smaller nondominant arch, often through a thoracotomy (Fig. 39.9). Patients with a right aortic arch and aberrant left subclavian artery are treated by division of the associated ligamentum arteriosum. Patients with a right aortic arch and aberrant left subclavian artery may have dilation of the proximal left subclavian artery, which is called a Kommerell's diverticulum. The Kommerell's diverticulum can cause direct compression of the airway or the esophagus. Resection of the Kommerell's diverticulum and reimplantation of the left subclavian artery may be required (Fig. 39.10).[10] Pulmonary vascular slings often require translocating the anomalous left pulmonary artery coming from the right pulmonary artery onto the main pulmonary artery. If complete tracheal rings are also seen in the presence of the pulmonary vascular sling, a slide tracheoplasty may be required (Fig. 39.11).[4,11] Patients with tetralogy of Fallot with absent pulmonary valve syndrome who develop respiratory distress during the neonatal period may benefit from prone positioning and often require mechanical ventilation.[8] Airway compression can be addressed surgically. Standard strategies include reducing the size of the pulmonary arteries and repositioning the pulmonary arteries anteriorly (LeCompte maneuver). There is not currently a consensus as to the best approach.[12–16]

# Pulmonary Hypertension and Postoperative Pulmonary Hypertensive Crisis

## Background

Pulmonary hypertension occurring during the postoperative period for congenital heart surgery is a serious condition resulting in significant morbidity and mortality.[17] Mortality related to postoperative pulmonary hypertension was reported to be as high as 20% during prior eras.[18] With a better understanding of the risk factors related to pulmonary hypertensive crises, surgical repair of congenital heart defects at younger ages, and the development of more effective treatments, the incidence of this condition has decreased significantly, with the current incidence estimated to be 2%–7%.[18]

## Risk Factors

Patients undergoing surgical repair of certain types of congenital heart disease are at higher risk of developing postoperative pulmonary hypertension. These include total anomalous pulmonary venous return, truncus arteriosus, transposition of the great arteries, ventricular septal defect (particularly with late repair), complete atrioventricular canal (with moderate to large ventricular septal defect component), and hypoplastic left heart syndrome.[18] Preexisting pulmonary hypertension as well as the presence of certain chromosomal abnormalities (trisomy 21, trisomy 18, trisomy 13) may also increase the risk of developing postoperative pulmonary hypertensive crises.[19] Cardiopulmonary bypass itself increases the risk of pulmonary hypertension because of endothelial injury, impaired production of nitric oxide, release of endothelin and thromboxane, and release of microemboli.[20,21]

Pulmonary hypoxia and ischemia during cardiopulmonary bypass and subsequent pulmonary reperfusion injury may also contribute to a state that may favor development of pulmonary hypertensive crises.[21]

## Pathophysiology

Pulmonary hypertensive crises are particularly dangerous, since they lead to both pulmonary as well as cardiac dysfunction. Increased pulmonary arterial pressure and resistance result in right ventricular dilation and right ventricular dysfunction. Right ventricular dilation leads to right-to-left shift of the interventricular septum and resultant compression of the left ventricle. Left ventricular compression decreases left ventricular compliance and therefore causes a decrease in pulmonary venous return and cardiac output.[21,22] Distention of the pulmonary arteries and resultant pulmonary edema leads to decreased lung compliance and hypoxia, hypercapnia, and respiratory acidosis.

## Evaluation and Monitoring

Pulmonary hypertensive crises may begin with nonspecific findings such as tachycardia and systemic hypotension.[21] Subsequent progression to bradycardia and poor perfusion may signal impending cardiac arrest. Unless there is an intracardiac shunt present, oxygen saturations may often be normal or near normal until profound clinical deterioration occurs. Several modalities are useful in detecting clinically significant pulmonary hypertension. Presence of an increased gradient between the arterial $pCO_2$ from a blood gas, and end-tidal $CO_2$ from capnography may indicate decreased pulmonary blood flow. Direct hemodynamic monitoring using intravascular catheters are also useful in the critical care setting. A right atrial line can assess right ventricular filling pressures and measure mixed venous oxygen saturations to estimate oxygen delivery. Pulmonary arterial lines can directly measure pulmonary arterial pressures.

Echocardiography is another important noninvasive tool to evaluate pulmonary arterial pressure. The systolic pulmonary arterial pressure can be estimated by measuring the peak systolic velocity of the tricuspid regurgitation jet from spectral Doppler. Similarly, mean pulmonary arterial pressures can be estimated measuring the end-diastolic velocity of the pulmonary insufficiency jet by spectral Doppler. Right ventricular size, right ventricular systolic function, and interventricular septal contour and position can all be assessed qualitatively using two-dimensional echocardiography.

## Treatment

Pulmonary hypertensive crises can be minimized through careful monitoring and treatment by several means. Appropriate sedation and pain control is extremely important to minimize pulmonary vascular resistance.[21] Fentanyl may be particularly useful in this setting, and paralysis is also used. Appropriate oxygenation and ventilation is important in maintaining low pulmonary vascular resistance, as both hypoxia and acidosis may cause pulmonary vasoconstriction. Although alkalosis promotes pulmonary vasodilation, high tidal volumes over time can damage alveoli and result in pulmonary edema. Conversely, inadequate tidal volumes can lead to alveolar collapse and resultant hypoxia.[22]

Current pharmacologic treatment of pulmonary hypertension involves the alteration of three mechanisms of pulmonary vasodilation: the nitric oxide/cyclic guanosine monophosphate (cGMP) pathway, the prostacyclin (PGI2)/cyclic adenosine monophosphate (cAMP) pathway, and the endothelin-1 pathway (see Chapter 35).[22] Inhaled nitric oxide is a selective pulmonary vasodilator, which has rapid onset of action. Inhaled nitric oxide has been used to treat postoperative pulmonary hypertension in patients who have undergone repair of obstructed total anomalous pulmonary venous return, mitral stenosis, and nonrestrictive ventricular septal defects. It has also been shown to be beneficial in single ventricle patients with Glenn and Fontan circulations by improving pulmonary blood flow, oxygen saturations, and central venous pressures.[24,25] Sildenafil has also been used as an adjunct to therapy when transitioning from inhaled nitric oxide to prevent rebound pulmonary hypertension.[26] Inhaled prostacyclin has also been shown to be effective in treating pulmonary hypertension in the postoperative setting.[27,28] Although bosentan therapy may be initiated in the intensive care setting, its effect on pulmonary hypertension is not rapid, so it is not effective in treating a pulmonary hypertensive crisis.

In addition to the pulmonary vasodilators mentioned previously, treatment of heart failure is critical in the management of patients with postoperative pulmonary hypertension. Milrinone infusion, in addition to decreasing pulmonary and systemic vascular resistance, improves left ventricular contractility and diastolic function. Systemic vasodilation may require initiation of a secondary agent. Norepinephrine, phenylephrine, and vasopressin may also be helpful in supporting cardiac function in the setting of pulmonary hypertensive crisis.[21,22]

# Pulmonary Vein Stenosis

## Background

Pulmonary vein stenosis is a rare entity associated with significant morbidity and mortality. Patients with significant pulmonary vein stenosis of multiple vessels have mortality reported as high as 47%.[29,30] Typically, pulmonary vein stenosis is seen in young children, often in the setting of congenital heart disease but occasionally occurring in association with normal intracardiac anatomy.[29,31] There is a reported association of acquired pulmonary vein stenosis with necrotizing enterocolitis in premature infants.[32] Pulmonary vein stenosis often progresses in severity within a short period of time, and a neoproliferative process is believed to drive rapid progression of the disease.[29,31] A form of pulmonary vein stenosis is now also being noted in some adults who have undergone electrophysiologic ablation procedures in the region of the pulmonary vein(s) for treatment of atrial fibrillation.

Focal pulmonary vein stenosis arising near the connection with the left atrium was first described in 1952, and this anatomic type is thought to represent approximately 60% of cases of pulmonary vein stenosis as determined in one multicenter study.[31,33,34] Diffuse stenosis of a longer segment from the junction of the left atrium can also be seen, as well as involvement of the entire pulmonary vein.[29] This process may represent a progression from limited involvement to more diffuse involvement of the pulmonary vein(s) over time. It is estimated that approximately 60% of patients have unilateral disease, of which most stenoses involve the left pulmonary veins. Approximately 40% of patients have bilateral pulmonary vein disease.[30]

## Presentation

Pulmonary vein stenosis can often present in the first few days to first few months of life. Symptomatically, it may present with tachypnea, failure to thrive, or repeated lower respiratory infections.[35] An accentuated second heart sound, right ventricular heave, and a short holosystolic murmur of tricuspid regurgitation may be present on physical exam.[34] Despite attempts at catheter-based or surgical intervention, pulmonary vein stenosis often progresses. The number of pulmonary veins involved influences the overall prognosis. Involvement of one or two pulmonary veins often suggests a good prognosis, whereas involvement of three or four pulmonary veins leads to a poor prognosis. Significant progression may result in severe pulmonary vein stenosis and even pulmonary vein atresia. Clinically, this results in worsening hypoxia, pulmonary edema, potential for pulmonary hypertensive crises, and hemoptysis, which may be life threatening.

## Imaging

Chest x-ray typically shows a reticular pattern of central pulmonary venous congestion. Echocardiography is useful in imaging the proximal pulmonary veins, and pulmonary stenosis is present by spectral Doppler if pulmonary venous flow velocities are greater than 1.6 m/second and do not return to baseline (Figs. 39.12 and 39.13). Noninvasive tomographic imaging modalities such as CT and MRI can directly visualize the narrowed pulmonary vein(s), although CT may offer advantages from faster acquisition, higher spatial resolution, and simultaneous evaluation of the lung parenchyma. Cardiac catheterization and angiography is the preferred imaging approach due to the ability to obtain selective pulmonary vein opacification with high resolution, as well as the ability to obtain hemodynamic measurements (Fig. 39.14).[29,35]

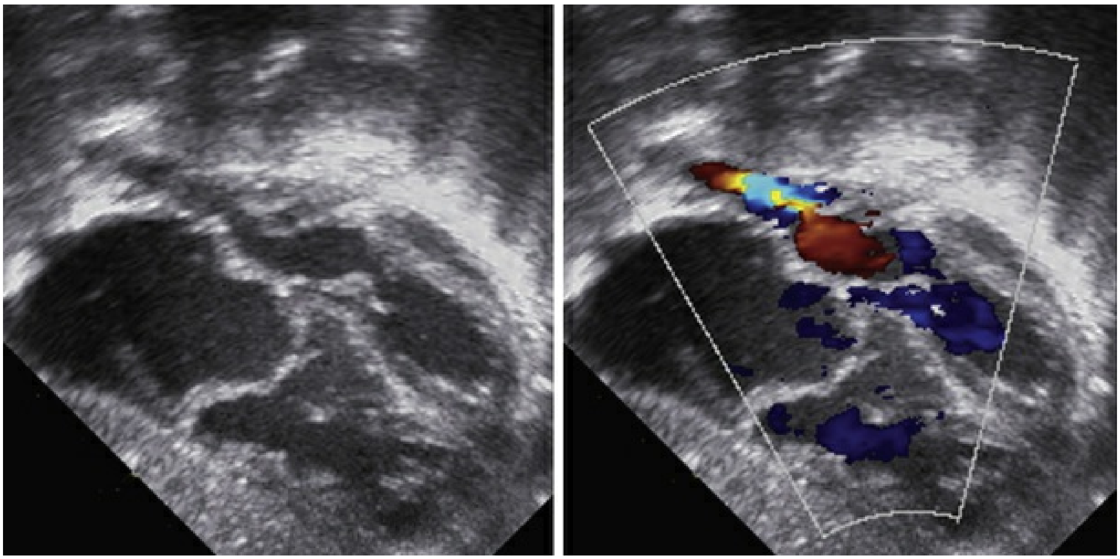

**FIG. 39.12** Discrete right pulmonary vein stenosis from apical four-chamber view by 2D and color Doppler echocardiography. The 2D picture shows a dilated right heart and discrete pulmonary vein stenosis. The color Doppler picture shows high-velocity flow at the level of pulmonary vein stenosis.

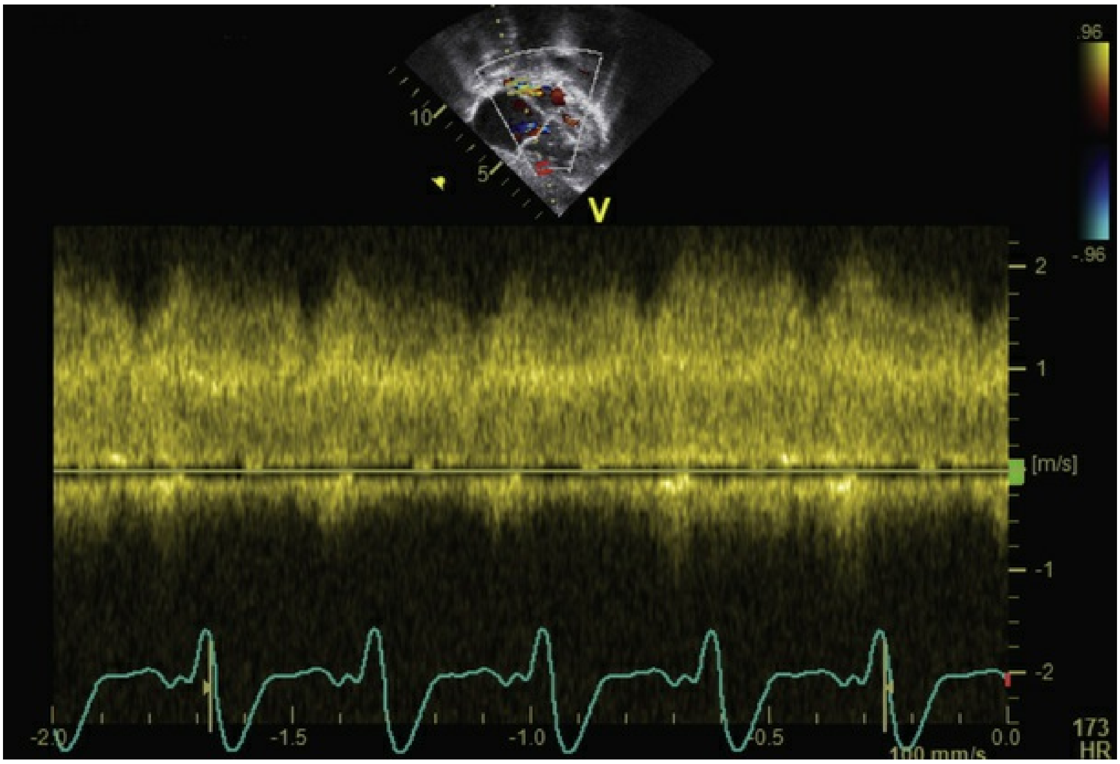

**FIG. 39.13** Spectral Doppler echocardiography demonstrates continuous high-velocity flow at the site of discrete pulmonary vein stenosis.

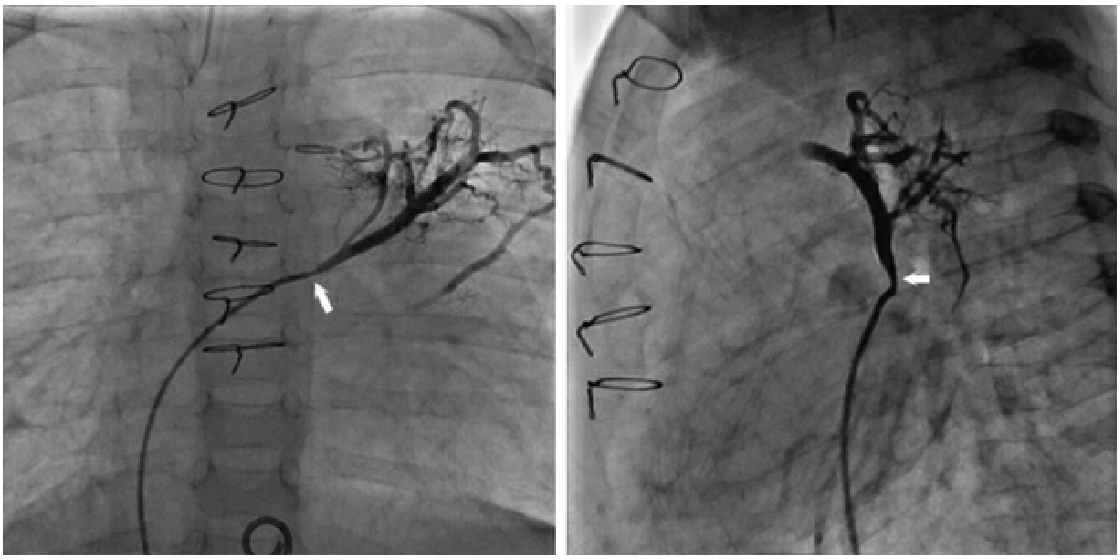

**FIG. 39.14** Discrete pulmonary vein stenosis of the left upper pulmonary vein with posteroanterior and lateral projections from biplane fluoroscopy. Left pulmonary vein is directly opacified by catheter. *Arrow* demarcates discrete narrowing of the pulmonary vein.

## Treatment

Stenotic pulmonary veins can be addressed surgically and in the cardiac catheterization laboratory, but outcomes remain suboptimal with current therapy. Surgical methods for repairing pulmonary veins include a standard patch repair versus a sutureless pericardial wall technique.[36] Restenosis or mortality was present in over half of patients, and there was no significant difference based upon the surgical technique used.[30,37] Conventional balloon angioplasty, use of cutting balloons, and placement of intravascular stents can improve the stenosis acutely, but repeated interventions are typically needed and are often not curative.[29,38]

# Reperfusion Pulmonary Edema in Children Undergoing Procedures for Tetralogy of Fallot, Pulmonary Atresia and Multiple Aortopulmonary Collateral Arteries

Tetralogy of Fallot with pulmonary atresia represents a complex and variable form of congenital heart disease, with anatomic classification based upon the source and distribution of pulmonary blood flow. Sources of pulmonary blood flow may range from the presence of true intrapericardial pulmonary arteries (with varying degrees of hypoplasia) supplied by a patent ductus arteriosus to pulmonary arteries in conjunction with major aortopulmonary collateral arteries (MAPCAs) or to MAPCAs alone. Not surprisingly, patients in the latter two groups present a particular challenge with regard to surgical palliation and complete repair.[39–41] The goal of surgical repair in the presence of MAPCAs supplying a significant portion of the pulmonary blood flow is to incorporate MAPCAs into the true pulmonary arteries by a “unifocalization” procedure, establish adequate pulmonary blood flow, and ultimately separate the systemic and pulmonary circulations by closure of the ventricular septal defect, if possible. In favorable situations, this may be performed as a single procedure but often requires multiple staged procedures.[39,40,42,43]

Inflammatory injury related to reperfusion of ischemic tissue is a well-recognized phenomenon. Pulmonary reperfusion injury occurring after balloon angioplasty of significant pulmonary artery stenosis or treatment of chronic thromboembolic disease has been described, presumably related to rapid improvement of blood flow to previously underperfused regions of the lung, and manifesting as localized pulmonary edema.[44,45] Maskatia and coworkers evaluated pulmonary reperfusion injury after unifocalization procedures for tetralogy of Fallot, pulmonary atresia, and MAPCAs and noted reperfusion injury to be common in this setting (65% of procedures). Risk factors in this patient population included bilateral unifocalization and severity of stenosis. There was not an association between presence of reperfusion injury and time to tracheal extubation.[46]

Asija and coworkers examined potential pathophysiologic mechanisms of this phenomenon in a similar group of patients by postoperative measurement of plasma biomarkers of alveolar injury and inflammation, including the receptor for advanced glycation end products (RAGE), intercellular adhesion molecule 1 (ICAM-1), and interleukin 6 (IL-6).[47] In this study, 50% of patients developed clinical evidence of reperfusion pulmonary edema. There were no significant differences however in levels of RAGE, ICAM-1, or IL-6 between patients with and those without reperfusion pulmonary edema measured at various time points, suggesting that the process does not appear to be associated with significant alveolar or vascular injury.[47]

Based upon our current knowledge, the entity of reperfusion pulmonary edema is common in certain conditions as described above, is self-limited, and does not appear to significantly alter postoperative course.[46]

## Pulmonary Disease Associated With the Fontan Repair of Single Ventricle Physiology

## Pathophysiology

The Fontan operation for single ventricle physiology,[48] which has undergone a series of surgical refinements and modifications over the years,[49,50] involves directing systemic venous return to the pulmonary circulation, thus allowing the functional single ventricle to serve exclusively as the systemic ventricle. Because blood flow to the lungs in this situation is “passive” and nonpulsatile, several situations may lead to impaired cardiopulmonary function and the so-called failing Fontan. These may include elevated central venous pressure, systolic and/or diastolic ventricular dysfunction, and significant atrioventricular valve regurgitation leading to elevated atrial and therefore pulmonary venous pressure, and/or elevated pulmonary vascular resistance.

In an attempt to minimize the occurrence of these complications, contemporary versions of the Fontan-type operation have included the creation of an intraatrial tunnel placing the inferior vena cava in direct continuity with the superior vena cava and right pulmonary artery (via end-to-side anastomosis of the superior vena cava to the right pulmonary artery),[49] or, more recently, placement of an extracardiac conduit directing caval flow to the pulmonary arteries.[50] In patients felt to be of higher risk, a small “fenestration” may be created between the Fontan circuit and the adjacent atrium, providing a source of right to left shunting to augment cardiac output and reduce systemic venous pressure.[51]

Despite these refinements, complications related to Fontan physiology do occur and may be cardiopulmonary in nature. As mentioned earlier, fenestration of the Fontan baffle may result in persistent cyanosis and resultant fatigue and exercise intolerance. Restrictive lung function and reduced aerobic capacity has been described in adult patients who have undergone the Fontan procedure.[52] As a result of post-Fontan physiology with passive pulmonary blood flow, augmentation of cardiac output during exercise is limited, and peak oxygen consumption is reduced.[53,54]

Venovenous collateral vessels and pulmonary arteriovenous malformations may also contribute to chronic cyanosis. Pulmonary arteriovenous malformations are commonly seen in situations where the hepatic venous drainage has not been incorporated into the Fontan circuit.[55]

## Clotting Abnormalities

Patients with Fontan-palliated single ventricle physiology may manifest clotting abnormalities related to deficiencies in protein C, protein S, antithrombin III, or increased platelet reactivity.[56,57] In the setting of nonpulsatile flow to the pulmonary arteries, the presence of prosthetic material in the Fontan circuit (intraatrial baffle, extracardiac conduit), decreased cardiac output, and presence in some patients of a baffle fenestration create a risk of thrombus formation that is not insignificant. This may lead to acute or chronic pulmonary emboli or systemic emboli. Chronic pulmonary microemboli may contribute to increased pulmonary vascular resistance and impaired Fontan physiology. Prophylactic antithrombotic regimens, particularly in patients with a Fontan fenestration, vary by specific patient characteristics and by center and may include low-dose aspirin and/or warfarin therapy.

## Pulmonary Vascular Resistance

As noted earlier, optimal Fontan physiology is dependent upon the presence of low pulmonary vascular resistance. Sildenafil, a phosphodiesterase type 5 (PDE5) inhibitor, acts as a pulmonary vasodilator and has been demonstrated to improve myocardial performance and exercise capacity after the Fontan operation.[58,59] Bosentan, an endothelin receptor antagonist, as well as inhaled prostacyclins, have also been shown to improve exercise capacity in Fontan patients.[60,61]

## Plastic Bronchitis

Plastic bronchitis is a rare, potentially life-threatening entity that is seen most commonly in patients who have undergone the Fontan procedure; it usually occurs in children.[62–64] A recent single-center review of Fontan patients at the University of Michigan estimated a prevalence of this condition ranging from 4%–14%.[65] The disease is characterized by the presence of large, dense mucus and fibrin plugs in the tracheobronchial tree with resultant cast formation. Depending on severity, patients may manifest cough, fever, dyspnea, wheezing, and symptoms of pulmonary obstruction. The casts may be noted on expectoration. They are classified histologically either as inflammatory casts composed of fibrin and eosinophilic infiltrates (type 1) or acellular casts containing mucin and fibrin without inflammatory infiltrate (type 2).[66] Type 2 (noninflammatory) casts are typically seen in the post-Fontan patient who has developed plastic bronchitis. Treatment of this condition can be extremely challenging. Pulmonary lymphatic abnormalities may contribute to this condition, and thoracic duct ligation or embolization have been reported as a potential treatment.[67–69] Treatment with aerosolized tissue plasminogen activator has also been utilized with reported benefit.[70,71]

## Heterotaxy Syndrome

In some patients, single ventricle anatomy may be seen in association with heterotaxy syndrome. Airway disease related to ciliary dysfunction should be evaluated in this setting due to the increased prevalence of ciliary abnormalities in patients with heterotaxy syndrome.[72] Ciliary dysfunction of the respiratory system is discussed in detail in Chapter 71.

# Pulmonary Complications Related to Cardiac Surgery and Cardiopulmonary Bypass

A number of factors may contribute to impaired pulmonary function after cardiac surgery and cardiopulmonary bypass. These may include the presence of postoperative atelectasis, pulmonary edema, and/or pleural effusions. Additional factors that may affect lung function may also be present, such as alterations of chest wall mechanics due to sternotomy, or impaired respiratory effort due to postoperative pain. Although uncommon, hemidiaphragmatic paresis or paralysis is an associated risk when surgical correction of congenital heart disease involves proximity to the phrenic nerve.

The period of ischemia to the pulmonary vascular bed followed by reperfusion after cardiopulmonary bypass promotes an inflammatory response that may lead to lung injury. Production of oxygen free radicals and activation of neutrophils, macrophages, and endothelial cells contribute to this process, leading to increased capillary permeability, pulmonary edema, impaired oxygenation, and increased pulmonary vascular resistance.[73,74] The entity of systemic inflammatory response syndrome (SIRS) also contributes to cardiopulmonary bypass related lung injury via complement activation and cytokine release.[75,76]

The administration of blood products during cardiac surgery and cardiopulmonary bypass may result in an inflammatory response and transfusion-related acute lung injury (TRALI). This syndrome is characterized by acute respiratory changes, hypoxemia, bilateral pulmonary infiltrates, fever, and hypotension temporally related to recent transfusion. In a multicenter study reported by Vlaar and coworkers patients who received transfusion during cardiac surgery with cardiopulmonary bypass demonstrated increased pulmonary capillary permeability compared to those patients who were not transfused. This finding was associated with packed red blood cell transfusion but not fresh frozen plasma or platelets.[77] In addition, Koch and coworkers found that patients undergoing cardiac surgery who received packed red blood cells or fresh frozen plasma developed more postoperative respiratory complications.[78] However, avoidance of blood product administration for cardiac surgery requiring cardiopulmonary bypass is generally not possible in the pediatric population due to small patient size/blood volume and associated limitations on hemodilution relative to the priming volume required for the cardiopulmonary bypass circuit.

## Conclusion

The pulmonary and circulatory systems are highly interdependent. Rare entities such as vascular rings and pulmonary vein stenosis must be considered in patients with respiratory symptoms that do not follow the expected clinical course. Pediatric cardiac surgery places patients at risk for reperfusion injury, pulmonary inflammation, and pulmonary hypertension. Single ventricle physiology can result in significant pulmonary dysfunction. Developing novel therapies to optimize pulmonary function under abnormal circulatory conditions will be critical in improving clinical outcomes.

# Lung Injury From Hydrocarbon Aspiration and Smoke Inhalation

*Ada Lee MD, Michael Bye MD*

## Epidemiology

In 2014, in the United States, 31,903 total hydrocarbon exposures were reported to poison control centers, and 9546 of these occurred in children less than 5 years old. There were 118,207 exposures to household cleaning substances in children less than 5 years old, resulting in the third leading cause of poisoning deaths in this age group in the United States.[1] The highest morbidity and mortality result from accidental ingestion in children less than 5 years of age.

## Etiology

Hydrocarbon toxicity resulting from the ingestion of petroleum solvents, dry-cleaning fluids, lighter fluids, kerosene, gasoline, and liquid polishes and waxes (mineral seal oil) continues to be a common occurrence in small children. This is in addition to the potential harm from additives such as heavy metals, pesticides, and camphor, all of which have potential systemic toxicity.[2–4] Kerosene heaters, cleaning fluids, furniture polishes, and liquid floor waxes are present in homes, too frequently within the easy reach of toddlers, and they account for the persistence of hydrocarbon poisoning. In one series of hydrocarbon ingestions, the material was stored in a standard beverage container almost one-third of the time.[5] The most commonly ingested materials are household cleaning products, solvents, and fuels; in some areas, kerosene ingestion is more common. In 2001, the US Consumer Product Safety Commission required child-resistant packaging for products with low viscosity and a significant concentration of hydrocarbons (>10% by weight).[6] Similar attempts were made by the European Union in 1997. Unfortunately, these regulations do not seem to have had a significant impact on the frequency of such poisonings.[7]

Although central nervous system (CNS) abnormalities (e.g., weakness, confusion, and coma), gastrointestinal irritation, cardiomyopathy, and renal toxicity all occur, the most common and the most serious complication is pneumonitis. Deaths from hydrocarbon poisoning are almost always from respiratory insufficiency.

## Pathology

Lung pathology in fatal cases includes necrosis of bronchial, bronchiolar, and alveolar tissue, atelectasis, interstitial inflammation, hemorrhagic pulmonary edema, vascular thromboses, necrotizing bronchopneumonia, and hyaline membrane formation.[8]

Experimental studies in rats reveal an acute alveolitis that is most severe at 3 days, subsides at 10 days, and is followed by a chronic proliferative phase that may take weeks to resolve.[9] Rats develop hyperemia and vascular engorgement of both large and small blood vessels within 1 hour of aspiration.[10] At 24 hours, there is a focal bronchopneumonia with microabscess formation. By 2 weeks, the process largely resolves, although some vascular engorgement and rare peribronchial inflammation persist. In humans, chest roentgenographic abnormalities persist for some time after physical findings have cleared, suggesting a similar prolonged recovery.

Dogs show different responses,[11] which also vary with the amount of kerosene ingested. A low dose causes destruction of alveolar epithelium, resulting in emphysema but insignificant airway involvement. More intense airway obstruction is seen in the high-dose group. At 1 hour after high-dose ingestion, intraalveolar edema and hemorrhage occur most prominently in the subpleural air spaces and those adjacent to large bronchi, suggesting induced interstitial inflammation. By 24 hours after ingestion, many airways show severe destruction and desquamation of the lining epithelium, resulting in near complete obliteration of the airways. The lumens are filled with degenerating neutrophils and scattered macrophages and lymphocytes. The surrounding lung parenchyma and the interstitia of the blood vessels show intense infiltration by macrophages and neutrophils, with microabscesses in the lung parenchyma. While most of the findings heal within a week, scattered areas of bronchiolitis obliterans may persist. By 2 weeks, much of the lung tissue has returned to normal, with rare areas of bronchiolitis obliterans. The severity of these dose-related changes can be explained by two characteristics of kerosene. First, it is a solvent that can dissolve cell walls and/or lipid lining layers, resulting in the desquamation of cells and fluid influx into the airways. Second, as a foreign substance that can penetrate the interstitium, it can provoke an intense inflammatory reaction. Since there are dose-related responses to kerosene with interspecies differences, accurate prediction of the process in humans is difficult.

## Pathophysiology

The risk for aspiration varies with the inherent properties of the hydrocarbon. Aspiration is much more likely to occur with a substance that has low surface tension, low viscosity, and high volatility, and low surface tension allows the substance to spread throughout the tracheobronchial tree. Low viscosity allows the substance to spread more readily and to seep deeper into the tissues. High volatility increases the likelihood of CNS involvement, presumably due to more rapid absorption into the bloodstream; highly volatile substances may also rapidly spread to the alveoli and immediately interfere with gas exchange.

Hydrocarbons increase surface tension by inhibiting surfactant,[12] which predisposes to alveolar instability and atelectasis. The instillation of artificial surfactant into the trachea of sheep following kerosene exposure resulted in significant improvement in oxygenation and mortality.[13] There is one case report of a 17-month-old child with ARDS from hydrocarbon aspiration who survived after treatment with surfactant.[14]

Pulmonary lesions are believed to be caused by direct aspiration of the hydrocarbon into the airways. This may occur either during the initial ingestion or during subsequent emesis. Small amounts of aspirated hydrocarbons may produce more serious disease than larger amounts in the stomach. Evidence that hydrocarbons are removed by the first capillary bed they encounter[15,16] reinforces the notion that pulmonary damage occurs from aspiration. Indeed, the liver and the lungs filter out sufficient amounts of kerosene to help prevent CNS damage.[15] Fatalities are rarely attributed to CNS involvement per se.

## Clinical Findings

Cough may appear within 30 minutes of aspiration or may be delayed for hours. Initially, auscultation of the chest may be normal or may reveal only coarse or decreased breath sounds. When severe injury occurs, hemoptysis and pulmonary edema develop rapidly, and respiratory failure may occur within 24 hours. Radiographic signs of chemical pneumonitis, when present, will develop within 2 hours after ingestion in 88% of cases and within 6–12 hours in 98%.[17,18] The findings vary from punctate, mottled densities to pneumonitis or atelectasis and tend to predominate in dependent portions of the lung (Fig. 40.1A). Air trapping, pneumatoceles, (see Fig. 40.1B),[19] and pleural effusions may also develop. The radiographic abnormalities reach their peak within 72 hours and then usually clear within days. A review of 16 children showed that children whose chest radiographs were to become abnormal did so by 24 hours after the ingestion, and most cleared within 2–3 weeks.[20]

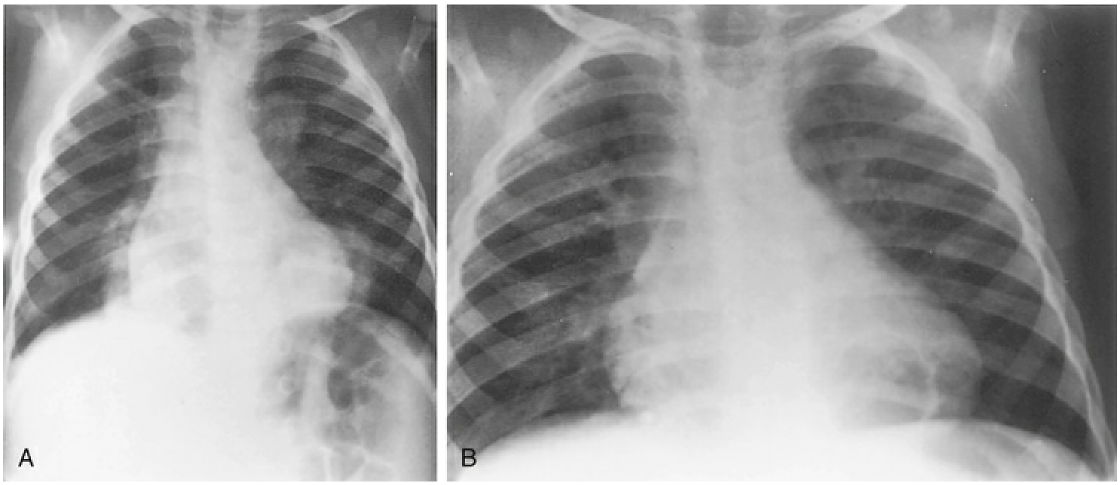

**FIG. 40.1** Hydrocarbon pneumonia. (A) Confluent sequential infiltrate is present in the left lower lobe. (B) Three weeks later, pneumatoceles are apparent; the large pneumatocele in the left lower lobe is at the site of the previous infiltrate. (From Felman AH. *Radiology of the Pediatric Chest.* New York: McGraw-Hill, 1987.)

Occasionally, the radiographic findings persist for several weeks. There is a poor correlation between clinical symptoms, physical findings, and radiographic abnormalities. In general, the radiographic changes are more prominent than the findings on physical examination and persist for a longer period. When pneumatoceles occur, they are likely to do so after a patient has become asymptomatic. They require several months for spontaneous resolution.

Blood gas studies reveal hypoxemia without hypercapnia, suggesting ventilation-perfusion mismatch or diffusion block. Destruction of the epithelium of the airways together with bronchospasm adds to the ventilation-perfusion abnormalities, and displacement of alveolar gas by the hydrocarbon vapors adds to the hypoxemia.

## Diagnosis and Differential Diagnosis

Diagnosis is elucidated from the history of hydrocarbon exposure. Differential diagnoses include bronchopneumonia, atelectasis, salicylate overdose, and other toxins.

# Management and Treatment

Initial management should comprise a history, physical examination, and chest radiograph. Because hydrocarbons do less damage when swallowed than when aspirated into the lungs, it is important to avoid emetics or gastric lavage. Some toxicologists recommend nasogastric lavage through a large bore tube in patients with a large amount of hydrocarbon with the potential for systemic toxicity if the patient presents within 1 hour of ingestion.[21,22] If the child had no symptoms at the scene or in the emergency room and has a normal chest radiograph, observation for 6–8 hours is important. If no symptoms develop, the child may be safely discharged home.[18] If an abnormality is detected by history, examination, or radiography, arterial blood gas analysis should be performed. Even if no symptoms develop, a repeat chest radiograph at 24 hours is a prudent measure. If results of examination and radiography are normal at 24 hours and the child has no further symptoms, discharge can occur after providing education and reassurance. Supplemental oxygen must be given if the child is hypoxemic. Adequate hydration should be maintained, but excessive fluid administration may be counterproductive, as the pulmonary pathology evolves. Case reports of rapid recovery of lung function and beneficial effects of lung mechanics and gas exchange were noted after early administration of intratracheal surfactant as early as initial presentation to the emergency room.[23,24] In animal studies, nebulized β2-agonist administered to sheep with combined smoke inhalation and burn injury resulted in improved lung function, airway clearance, and reduced pulmonary edema.[25] Although clinical data in humans is lacking on the use of β2-agonist in inhalation injury, some have suggested a trial of bronchodilators if respiratory symptoms progress. Hypoxemic respiratory failure should be treated with mechanical ventilation and positive end-expiratory pressure. If the child fails conventional mechanical ventilation, both extracorporeal membrane oxygenation (ECMO)[26] and high-frequency jet ventilation[27] have been successful in improving oxygenation and allowing survival.

Although superimposed bacterial infection is a potential concern, there is no evidence that this is a common occurrence. Because leukocytosis and fever are common after hydrocarbon aspiration, it is often difficult to detect bacterial superinfection. One thoughtful review concluded that bacterial complications are rare.[28] Until there is further evidence to the contrary, antimicrobial therapy should be reserved for patients who are severely compromised by malnutrition, debilitation, or an underlying disease or in whom the pneumonia is especially severe. Evolving evidence of infection on serial Gram stains of secretions from the endotracheal tube could be an indication for antimicrobials. Because airway closure and collapse are a significant part of the disease, continuous distending airway pressure is desirable to maintain functional residual capacity (FRC) and to keep the concentration of inspired oxygen in safe ranges. Studies in animals and humans show no therapeutic or prophylactic role for corticosteroids.[29–31]

## Prevention

Prevention of the accidental ingestion of products containing hydrocarbons must be a high priority. Educating parents to keep potentially toxic materials out of the reach of young children seems obvious. Education about storage of such materials and avoiding containers that children associate with potable liquids must be stressed. Prevention of nonintentional poisonings includes clearly labeling containers that contain hydrocarbons. If kerosene heaters are used in the home, the kerosene must be kept out of the reach of children.

## Prognosis

Prognosis and clinical improvement depends on the type, volume, and pH of the substance aspirated. Long-term follow-up studies of pulmonary function in patients with hydrocarbon pneumonitis indicate residual injury to the peripheral airways. A study of 17 asymptomatic children 8–14 years after a hydrocarbon pneumonitis showed abnormal lung function in 14 (82%). The most common abnormalities were an elevated ratio of residual volume to total lung capacity, an increased slope of phase III, reduced forced expiratory volume in 1 second ($FEV_1$) and a high volume of isoflow[32]; these results indicate small airway obstruction and gas trapping. When radiographic changes accompany the ingestion of hydrocarbons, this same pattern of abnormal lung function is detected 10 years later, even in otherwise asymptomatic subjects. However, the frequency of airway reactivity appears to be normal.[33] Most children survive without serious complications, but some may progress to respiratory failure and death.

## Hydrocarbon "Sniffing"

Deliberate inhalation of volatile hydrocarbons to induce a state of euphoria is common among adolescents. It is estimated that 13% of adolescents have used inhalants at one time or another.[34] Unlike other forms of drug abuse, this is more common among those in the seventh to ninth grades.[35,36] The euphoria of mild intoxication may be accompanied by mild nausea and vomiting. Prolonged exposure may lead to violent excitement followed by CNS depression, unconsciousness, and coma. Large doses of halogenated hydrocarbons, especially when combined with exertion, excitement, and hypercapnia, may be associated with dysrhythmias and death. Medullary depression and respiratory paralysis are generally accepted as the mechanism of death in most gasoline inhalation fatalities. Strong psychological dependence may develop in some sniffers. Acute hypoxemia at the time of inhalation and shortly thereafter is not uncommon as a result of displacement of alveolar gas by the inhaled substance. However, this is usually transient and not significant. Lung injury per se from hydrocarbon sniffing has not been described. A toluene embryopathy has been described in infants born to mothers who sniffed toluene,[37] although the "polypharmacy" often used by the mothers may confound the data.[38]

## Respiratory Complications of Smoke Inhalation

## Epidemiology

In 2014, there were 494,000 structural fires in the United States; of these, 386,500 were residential structural fires.[39] Death from fire is the seventh leading cause of unintentional injury death in the United States in 2014.[40] The United States ranks 10th out of 24 developed countries in fire deaths.[41] Those at greatest risk are children younger than 4 years of age; African-American and Native American males; those over 85 years of age, and the poor.[42] In 2014, 3275 civilians died in fires in the United States.[39] A great deal of the morbidity and mortality in victims of fires results from pulmonary injuries due to smoke inhalation.[43] The severity of the lung injury depends on (1) the nature of the material involved in the fire and the products of incomplete combustion that are generated and (2) whether the victim has been confined in a closed space. The subject's minute ventilation also plays a role. The deeper and more rapidly the victim breathes, the greater the amount and degree of deposition of toxic materials into the airways and alveoli. The decreased inspired oxygen concentration that results from the fire stimulates compensatory hyperapnea in humans.

## Etiology

Fire-related injuries and death occur as a result of structural and outside fires. Isolated smoke inhalation injury can occur but may be complicated by thermal or chemical burns to the airways.

## Pathogenesis

The pathogenesis of lung injury from smoke inhalation includes thermal and chemical factors. Because the upper airway is such an effective heat exchanger, most of the heat from inhaled smoke is dissipated before the inhaled material reaches the carina. Direct thermal damage, therefore, primarily affects the supraglottic airways. Only with steam, which is unusual in most fires, or with prolonged exposure to high ambient temperatures, will there be thermal injury to the intrathoracic airways.

Depending on the material involved in fires, a wide variety of noxious gases may be generated. These include the oxides of sulfur and nitrogen, acetaldehydes, hydrocyanic acid, and carbon monoxide (CO). Irritant gases such as nitrous oxide or sulfur dioxide may combine with lung water to form corrosive acids. Aldehydes from the combustion of furniture and cotton materials induce denaturation of protein, cellular damage, and pulmonary edema. The combustion of wood generates considerable quantities of CO and carbon dioxide. Plastics, if heated to sufficiently high temperatures, may be the source of very toxic vapors. Thus, chlorine and hydrochloric acid may be generated from polyvinyl chloride; hydrocarbons, aldehydes, ketones, and acids from polyethylene; and isocyanate and hydrogen cyanide from polyurethane.[44] Although the particulate matter carried in the smoke (soot) probably does not in itself produce injury, toxic gases may be absorbed on the surface of the carbon particles and carried into the lungs; the soot particles may also be responsible for inducing reflex bronchoconstriction.

## Carbon Monoxide Poisoning

CO poisoning is an especially serious complication of smoke inhalation that occurs soon after exposure. While smoke inhalation is the most common cause of inadvertent CO poisoning, other causes include poorly functioning home heating systems; inadequate ventilation for fuel burning systems (e.g., gas grills, kerosene heaters, and camp stoves); and motor vehicles idling in poorly ventilated areas. Some of these can also be the sources for intentional poisoning. The toxicity results from the combination of CO with hemoglobin to form carboxyhemoglobin (COHb), leading to severely impaired tissue oxygenation. The CO displaces oxygen from hemoglobin, reducing the delivery of oxygen to the tissues. CO not only has a higher affinity for hemoglobin than oxygen but also shifts the oxyhemoglobin dissociation curve to the left (Fig. 40.2).[45] For this reason, the toxicity of CO poisoning is greater at high altitude and in the presence of anemia. It is critical to remember that although the oxygen content of the arterial blood is low in CO poisoning, the partial pressure of oxygen in arterial blood ($PaO_2$) is not reduced. Because the carotid body responds to $PaO_2$, ventilation may not be stimulated until acidosis develops.

Together with the fact that COHb is bright red, this makes the clinical diagnosis very difficult. The bright red color of the blood also makes the currently available oximeters unreliable. If there is a suspicion of CO poisoning, an ***arterial*** blood gas ***must*** be obtained along with COHb levels. CO also binds to myoglobin, resulting in anoxia of muscle cells. With prolonged exposure, CO binds to cytochrome oxidase, impairing mitochondrial function and reducing production of adenosine triphosphate. Both of these actions impair normal cellular function.

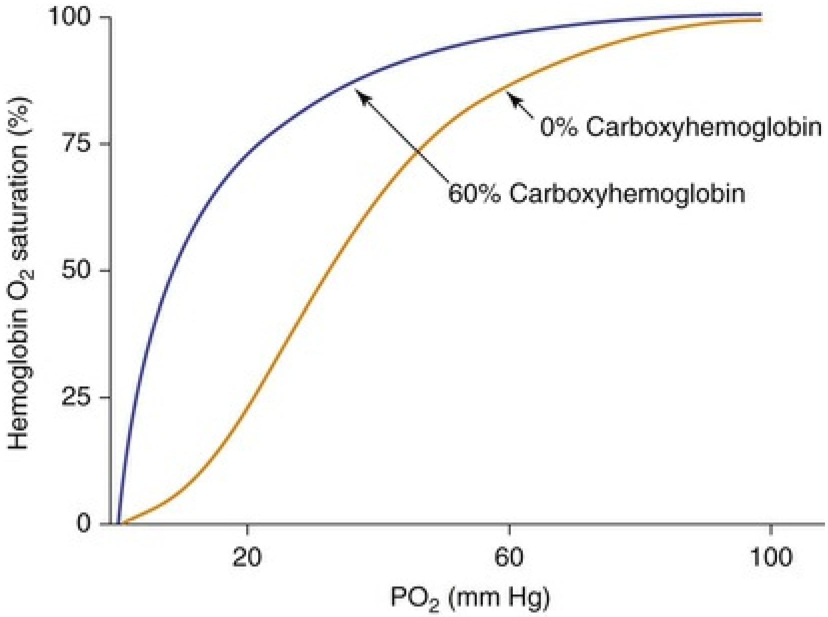

**FIG. 40.2** Oxygen–hemoglobin dissociation curve. The presence of carboxyhemoglobin shifts the curve to the left and changes it to a more hyperbolic shape. This results in a decrease in oxygen-carrying capacity and impaired release of oxygen at the tissue level. (From Ernst A, Zibrak J. Carbon monoxide poisoning. *N Engl J Med.* 1998;339:1603-1608.)

## Pathology

Various pathologic lesions are found in smoke inhalation. Part of the variability in pathology may be attributed to differences in the toxic products generated in fires. However, many of the pulmonary changes may not result simply from the direct chemical injury to the respiratory tract. Rather, they may reflect secondary circulatory, metabolic, or infectious complications of surface burns or may be induced by the administration of oxygen, mechanical ventilation, and the administration of excessive volumes of intravenous fluids.

Animal models of the pathology have been of limited value, because steam rather than pure smoke was usually used, and the modifying effects of the upper air passages were eliminated by using tracheal cannulas. Experimental evaluation of the response to smoke has been performed in anesthetized and intubated sheep, kept light enough to breathe spontaneously. Even in these animals, any protective effects of the upper airway were bypassed. Smoke was generated by burning material such as dyed cotton toweling. The smoke was then insufflated into the lungs. In sheep, a volume of 20 cc/kg for 12 breaths and an inspiratory time of 3–4 seconds produced physiologic effects similar to natural smoke inhalation, including mean COHb levels of 45%.[46]

The initial pathologic changes are tracheobronchitis. The greater the tidal volume of the insufflated smoke, the more intense the tracheobronchitis. With sufficient smoke quantity, denudation of the tracheal epithelium occurred, most likely from disruption of the cell-cell and the cell–basal layer adhesions.[47] With much larger volumes, acute pulmonary edema caused by increased pulmonary vascular permeability occurred within 30 minutes.[48] The degree of atelectasis also correlated with the amount of smoke insufflated. Subsequent airway edema only occurred in those animals given large tidal volumes of smoke.[46] The degree of hypoxemia over the 24 hours studied did not correlate with the tidal breath size but was constant for a given total smoke exposure. This suggests that the gas exchange deterioration was based more on the airway pathology than on the alveolar atelectasis or edema.

A group of infants studied postmortem after accidental exposure to smoke in a newborn nursery[49] was found to have necrosis of bronchial and bronchiolar epithelium with vascular engorgement and edema together with the formation of dense membranes or casts that partially obstructed the large and small airways. Bronchiolitis and bronchopneumonia were present in some, as were interstitial and alveolar edema. There was carbonaceous material in the alveoli with alveolar hemorrhage.

Electron microscopic studies of 10 fatal cases of smoke inhalation following a hotel fire revealed interstitial and alveolar edema as well as engorgement of alveolar vessels.[50] Carbon particles were seen within alveolar macrophages. Type I pneumocytes showed more injury than was seen in the pulmonary endothelial cells. Patients who died after severe surface burns have had necrotizing bronchitis and bronchiolitis with intraalveolar hemorrhage, hyaline membrane formation, and massive pulmonary edema. In these patients, it is difficult to know how much to attribute to direct pulmonary injury from smoke or to the complex metabolic, infectious, chest wall, and circulatory derangements that complicate surface burns and result in acute respiratory distress syndrome (ARDS). However, sheep exposed to surface burns plus smoke inhalation sufficient to raise the COHb levels to 25%–30% fared much worse than the sheep exposed to surface burns alone. The burn/inhalation group had greater amounts of lung lipid peroxidation products in bronchoalveolar lavage and at autopsy even without evidence of pulmonary infection or ARDS.[51]

## Pathophysiology

Severe damage to the upper air passages leads to stridor with increased extrathoracic resistance. Upper airway obstruction usually occurs within 24 hours of injury. This increases the work of breathing and can lead to alveolar hypoventilation. Inflammatory changes in the airways lead to ventilation/perfusion mismatch, exaggerating the hypoxemia. Depending on the severity and distribution of the airway obstruction, there may be atelectasis or air trapping. The latter is especially likely with premature closure of the small airways. Altered surfactant function predisposes to atelectasis. Although reflex bronchoconstriction may contribute to the increase in airway resistance, it is difficult to assess the magnitude of its contribution, because airway resistance is already high as a result of bronchial and bronchiolar edema and inflammation.

Smoke is a mixture of gases and particulate matter generated from burning substances. The toxic effects of smoke are primarily seen when animals are exposed to whole smoke. When the particle phase of the smoke was filtered out, there were neither acute nor delayed toxic effects on lung function or gas exchange.[52] Since many of the oxidants are in the gas phase as well in whole smoke, it is possible that only those toxins carried on the smoke particles remain in the airway long enough to elicit an inflammatory response.

Pulmonary edema plays a prominent role in the pathophysiology of lung injury from smoke inhalation.[44] Studies in adults demonstrate increased extravascular lung water without a concomitant increase in pulmonary capillary wedge pressure. Studies in sheep reveal increased lung lymph flow and an increase in the lymph/plasma ratio of protein, suggesting increased permeability of the alveolar capillary membrane.[53] Increased bronchial circulation contributed to the pulmonary edema. Nitric oxide at extremely elevated levels acts as a free radical and potentiates the inflammatory response. Inhibition of inducible nitric oxide synthase reverses the loss of hypoxic pulmonary vasoconstriction and attenuates acute respiratory distress syndrome.[54,55]

Other products of combustion increase the damage. In dogs, acrolein found in herbicides and cigarette smoke results in delayed-onset pulmonary edema. Pure smoke, and smoke with added hydrochloric acid, did not have the same effects.[56] An animal model showed increased pulmonary vascular resistance and decreased cardiac output concomitant with increased secretion of leukotrienes C4, D4, and E4. Pretreatment with a leukotriene antagonist markedly attenuated and delayed those cardiovascular changes.[57] Additional studies in sheep suggest that the acrolein-induced pulmonary edema and pulmonary hypertension are mediated by cyclooxygenase products, because pretreatment with cyclooxygenase inhibitors blocks the cardiorespiratory changes.[58] The acute pulmonary edema associated with very high-dose cotton smoke exposure in sheep is blocked by a combined cyclooxygenase and leukotriene antagonist, but not by indomethacin, a cyclooxygenase inhibitor. Both agents block the elevated airway resistance and hypoxemia that presumably occur as a result of acute bronchoconstriction. Prolonged exposure to acrolein in a kitchen resulted in severe respiratory distress in a previously healthy 27-month-old child who developed bronchiectasis 18 months after the initial exposure.[59]

Oxidants directly from the products of combustion also contribute to airway damage, closure, and atelectasis.[60] Early therapy with aerosolized deferoxamine-pentastarch in sheep exposed to cotton smoke attenuated these findings.[61] It is not clear whether the deferoxamine was acting directly as an antioxidant or reducing the free iron released in the airway.

Neutrophil-mediated proteolytic activity has been implicated in the airway pathology. Sheep treated intravenously with the synthetic protease inhibitor gabexate mesilate after insufflation with cotton smoke had a significant reduction in transvascular fluid and protein flux and were able to maintain better gas exchange than a vehicle-treated control group.[62] Impaired chemotactic and phagocytic function of the alveolar macrophage after smoke inhalation increases the risk for pulmonary infection several days after the acute event.

Any inhaled cyanide binds to the intracellular cytochrome system, inhibiting cell metabolism and the production of adenosine triphosphate. While all cells contain the enzyme rhodanese, which can convert hydrocyanide to thiocyanate, this capability is outstripped by continued or high levels of cyanide. The thiocyanate is excreted in the urine, assuming normal renal blood flow and urine output.[63]

## Clinical Findings

The initial respiratory assessment of a victim of a fire should focus on hypoxemia. Patients may have facial burns, singed nasal hairs, carbonaceous sputum, or soot in the proximal airway. Blistering or edema of the oropharynx, hoarseness, stridor, and upper airway mucosal lesions may be evident. Symptoms include tachypnea, dyspnea, cough, and cyanosis. Chest retractions may be present, and auscultation may reveal wheezing, crackles, or rhonchi. Oxygen should be administered while arterial blood gas studies, including CO levels, are drawn. The clinical manifestations of CO poisoning vary with the level of COHb. Mild intoxication leads to headache, diminished visual acuity, irritability, and nausea. COHb levels greater than 40% produce confusion, hallucination, ataxia, and coma. CO may increase cerebral blood flow, the permeability of cerebral capillaries, and the cerebrospinal fluid pressure. CO may also have long-term effects on the CNS, and myocardial dysfunction and irritability can result directly from CO, as well as from hypoxemia.

Patients assessed immediately at the scene of a fire have elevated blood cyanide concentrations, and the cyanide levels of victims who die because of smoke inhalation are significantly higher than the levels of survivors. Blood cyanide levels correlate with CO levels, and plasma lactate levels were better correlated with cyanide levels than with CO level. A plasma lactate concentration above 10 mM in the emergency department is a sensitive indicator of cyanide poisoning.[64]

Maximum inspiratory and expiratory flow-volume curves and flexible fiberoptic nasopharyngoscopy or bronchoscopy have been helpful in the early assessment of the extent of supraglottic or tracheobronchial injury and the likelihood of subsequently developing airway obstruction.[65] Although there may be some delay in the clinical evidence of respiratory tract injury resulting from smoke inhalation, manifestations of respiratory disease will usually develop within 12–24 hours. Absence of roentgenographic pulmonary disease is not very helpful in early diagnosis, because abnormal findings may lag several hours or more behind auscultatory or physiologic evidence of damage.

Respiratory insufficiency may also occur as the result of airway obstruction anywhere from the supraglottic airways to the alveoli. It may be difficult to localize the level of obstruction; therefore, whenever there is clinical evidence of severe obstruction, the upper airways should be assessed by direct laryngoscopy before swelling of the head, neck, or oropharynx make this examination difficult. Fiberoptic bronchoscopy may be very useful to evaluate the extent of mucosal damage, but intense vasoconstriction in hypovolemic patients may mask the findings.[66]

Acute CO poisoning is also associated with acute myocardial injury and a delayed neuropsychiatric syndrome, which in children will lead to cognitive defects and sometimes to focal deficits. However, the mechanism of action of these complications has not been elicited.

## Diagnosis and Differential Diagnosis

Diagnosis of smoke inhalation injury is largely based on history of smoke exposure in a closed space. Facial burns, singed nasal hairs, soot in the nasopharynx, or voice changes may help support the diagnosis. Patients with smoke inhalation with superimposed altered mental status require a careful evaluation for hypoxia secondary to either pulmonary injury or impaired oxygen utilization at the cellular level. Differential diagnoses include acute respiratory distress syndrome, aspiration pneumonitis, pneumonia, asthma, pulmonary embolism, and cyanide poisoning.

## Management and Treatment

The initial treatment should focus on reversing CO poisoning, if present, by the administration of high concentrations of humidified oxygen. CO levels may be reduced by half in about an hour when the patient breathes 100% oxygen. If severe CO poisoning is suspected, it is helpful to administer oxygen by nonrebreathing mask at flow rates higher than the victim's minute ventilation to achieve concentrations close to 100%. If results of clinical examination or arterial blood gas studies suggest alveolar hypoventilation, mechanical ventilation is necessary. Subsequently, the administration of oxygen may be important because of the hypoxemia resulting from bronchiolitis and alveolitis with premature closure of small airways. Constant positive distending airway pressure may also be necessary to maintain reasonable levels of $PaO_2$ without using excessively high and potentially toxic concentrations of inspired oxygen for prolonged periods of time.

Controversy exists regarding the importance of, and need for, hyperbaric oxygen in the management of CO poisoning. Hyperbaric oxygen at 2–3 atmospheres markedly hastens the decline of COHb levels, reducing the half-life of COHb to 20–25 minutes. However, the advantages of hyperbaric oxygen therapy may be offset by complications during transfer to the hyperbaric chamber. While some clinicians claim that all patients with significant COHb levels should be sent to a hyperbaric chamber, there is scant evidence for this approach.[63] There are no clear guidelines on the use of hyperbaric oxygen therapy in the treatment of CO poisoning. One review suggests using hyperbaric therapy for children with COHb levels of 25% or greater if symptomatic and for any with levels of 40% or higher.[67] The potential risks of the hyperbaric chamber include oxygen toxicity to the lung, the fact that patients are not amenable to appropriate observation and intervention while they are in the chamber, and the need for tympanotomy. More data are necessary to adequately assess the risks and benefits of hyperbaric oxygen in the therapy of CO poisoning in children related to fires.[68] Systematic reviews have not established whether hyperbaric oxygen therapy given to adult patients with CO poisoning reduces the incidence of adverse neurological outcomes[69]; consequently, its use in children remains controversial.

Endotracheal intubation may be necessary for a patient with any of the following conditions: (1) severe burns of the nose, face, or mouth, because of the likelihood that nasopharyngeal edema and obstruction will develop; (2) edema of the vocal cords with laryngeal obstruction; (3) difficulty handling secretions; (4) progressive respiratory insufficiency requiring mechanical ventilation; and (5) altered mental status that decreases minute ventilation and diminishes the protective reflexes of the airway. Regardless of whether the glottis is bypassed by endotracheal tube or tracheostomy tube, constant positive airway pressure or positive end-expiratory pressure helps minimize edema and improve oxygenation. Noninvasive positive pressure ventilation may be attempted in patients with acute respiratory decompensation who are otherwise hemodynamically stable, conscious, and without extensive and deep facial burns or trauma. This mode of ventilation has been reported to be effective in avoiding intubation/reintubation in a group of patients with burn-associated acute respiratory failure.[70] However, the risk of upper airway obstruction must be taken into account when selecting patients for noninvasive ventilation.

In addition to the increased airway resistance resulting from edema in and around the walls of airways, it is likely that some reflex bronchoconstriction occurs from irritation of airway receptors. This is more likely to occur in subjects with preexisting lung disease such as asthma or cystic fibrosis or in cigarette smokers. For this reason, it may be reasonable to administer inhaled bronchodilators.

Airway obstruction by cast material containing fibrin often accompanies smoke inhalation injury. In sheep with acute lung injury following burn and smoke inhalation injury, a combination of nebulized heparin and recombinant antithrombin has been demonstrated to improve pulmonary gas exchange and lung compliance, with decreased pulmonary edema, and airway obstruction.[71] In children with burn and smoke inhalation injury, nebulized heparin and *N*-acetylcysteine significantly decreased incidence of reintubation for progressive pulmonary failure, decreased incidence of atelectasis, and reduced mortality.[72] Similarly, in adults with smoke inhalation injury, nebulized heparin and *N*-acetylcysteine reduced lung-injury scores.[73]

Coagulation factors should be monitored as significant coagulopathy with prolonged partial thromboplastin time (PTT) has been associated with aerosolized heparin and *N*-acetylcysteine therapies for inhalation injury.[74] As in many other respiratory conditions, the role of chest physiotherapy is poorly defined. Nevertheless, mucociliary clearance is clearly impaired. The encouragement of deep breathing and cough, or gentle endotracheal suction in the presence of endotracheal intubation, coupled with postural drainage would seem to be reasonable. Using a cough-assist device might be considered.

Although corticosteroids are frequently advocated in the hope of suppressing inflammation and edema, most controlled studies fail to demonstrate a significant effect. Thus, it is difficult to marshal strong support for their use. Furthermore, long-term steroid therapy in victims of fires increases the susceptibility to infection. Until further evidence is available, the empirical use of corticosteroids is discouraged. One review suggests using corticosteroids only for evidence of peripheral airway obstruction, other illnesses requiring steroids, or recent use of steroids.[67] At the experimental level, ibuprofen (but not indomethacin) when given immediately after smoke inhalation injury prevented the development of pulmonary edema.[75] As animal studies further elicit the basic mechanisms of the events occurring within the airways and parenchyma, specific agents may become available to correct the pathophysiology.

Available evidence indicates that antimicrobial agents do not prevent subsequent infection and may only predispose to infection with resistant organisms. Because fever, elevated white blood cell count, and increased erythrocyte sedimentation rate may all result from smoke inhalation and because the chest roentgenogram may show nonspecific opacities that represent either atelectasis or edema, it may be extremely difficult to establish the presence of an infection in the absence of positive blood cultures or a positive Gram stain of airway secretions. It would seem preferable to reserve antimicrobial therapy for patients in whom there is clinical deterioration despite supportive therapy. Changes in the amount, nature, or color of the secretions should raise the suspicion of a bacterial superinfection, which should be confirmed by Gram stain or culture. Because the prevention of infection is clearly an important part of the therapy in victims of fires, aseptic care of the trachea and humidifying equipment is essential. In addition, in a retrospective analysis of children, high-frequency percussive ventilation was associated with a lower incidence of pneumonia.[76]

While dogs benefited from surfactant after smoke exposure,[77] rabbits did not.[78] To our knowledge, there are no data in human subjects. Smoke-exposed sheep did worse with ECMO support than with conventional mechanical ventilation. The ECMO was associated with pulmonary sequestration of leukocytes, increased pulmonary thromboxane $B_2$, increased blood-free wet/dry lung weight ratios, and more significant hypoxemia at 24 hours after identical degrees of smoke exposure.[79] Two children with inhalation injury and resultant respiratory failure refractory to conventional mechanical ventilation were successfully treated with ECMO.[80]

## The Relationship of Pulmonary Injury From Smoke Inhalation to the Pulmonary Complications of Surface Burns

Pulmonary damage from smoke inhalation generally declares itself during the first 24 hours. Individuals with widespread surface burns may develop pulmonary complications after several days, but these late complications are not the result of direct chemical or thermal injury. It is more likely that late pulmonary injury is attributable to metabolic, infectious, or circulatory derangements complicating the surface burns.[65]

Surface burns may be directly and indirectly related to pulmonary pathophysiology. The large amounts of intravenous fluids usually given to counteract ongoing surface and “third-space” losses in the tissues may increase pulmonary edema through two mechanisms. First, there may be pulmonary vascular engorgement from diminished myocardial function due to CO poisoning, the initial hypoxia, and other toxins involved in the fire. Second, the diffuse inflammation within the airways increases vascular permeability with fluid leak into the areas of gas exchange, worsening the hypoxemia and causing additional pulmonary edema. Careful monitoring of fluid balance is critical in these children.

A second indirect relationship between the surface burns and the lung exists in the infection area. Clearly, the postburn lung is at risk for pneumonia. Organisms may also enter the body through the skin at the burn site, and scrupulous attention to the burn sites is necessary to reduce this possibility. The lung can be directly infected in pneumonia or as part of the sepsis syndrome.

The skin surface and lung may be directly related with severe skin burns of the thorax or upper abdomen. Chest wall edema or eschar formation, in addition to the pain at the skin site, increase the risk for hypoventilation and atelectasis.[81] Attention must be directed to skin manifestations (e.g., eschars) and pain control. Pain control with narcotics may increase the risk for hypoventilation, but this can be easily monitored, and adequate pain control is important for children with burns.

## Prevention

Prevention is paramount when discussing smoke inhalation. Strategies for reducing fire-related injuries include increasing public fire safety education aimed at encouraging homeowners and property managers to install and maintain use of smoke alarms. Carbon monoxide detectors should be utilized in locations at risk for carbon monoxide exposure. Finally, families should develop and practice fire escape plans.

## Prognosis

Children with acute pulmonary injury from smoke inhalation generally recover once supported though the initial phase of illness. The severity of pulmonary parenchymal injury depends on the duration and type of inhalant exposure. The impact of smoke inhalation on long-term lung function in children may be dependent upon their stage of lung development at the time of injury as well as confounding lung injury sustained from acute respiratory distress syndrome, pneumonia, or acute lung injury. There are limited studies of the effect on lung function in children with smoke inhalation injury. Obstructive and mixed obstructive and restrictive defects have been reported in children 8 years following thermal injury.[82] Long-term sequelae of tracheal stenosis, bronchiectasis, interstitial fibrosis, and bronchiolitis obliterans may rarely be observed.

# Drowning

*Christopher J.L. Newth MD, FRACP, FRCPC, Jürg Hammer MD, Andrew H. Numa MBBS, FRACP, FCICM*

## Definitions

A uniform definition of drowning was agreed upon during the World Congress on Drowning in Amsterdam, The Netherlands, in 2002.[1] Drowning is now defined as "a process resulting in primary respiratory impairment from submersion/immersion in a liquid medium." The term "drowning" now encompasses both fatal and nonfatal outcomes of immersion, and "near-drowning" is no longer used.

## Epidemiology

Drowning occurs in all age groups and is responsible for approximately 4000 deaths per annum in the United States, with a mortality frequency of 12–18 deaths per million person years.[2,3] The highest mortality rates of approximately 30 deaths per million person years have been observed in the 0–4 and 15–19 year age groups,[2,3] although there is some evidence that both mortality and hospitalization rates have declined over the last 2 decades.[4] In the first year of life, drowning mortality in the United States is 63 per 100,000 live births.[3] Worldwide, drowning is the 11th most frequent cause of death in the 0–4 years age group, the third most frequent cause of death in children aged from 5 to 14 years,[5] and the second leading cause of injury-related death in childhood.[6] The vast majority of drowning deaths occur in non-Western countries; in Bangladesh, more children in the 1–4 years age group die from drowning than from diarrhea or respiratory infection.[7] Even in a well-developed country such as Australia, where drowning accounts for less than 1% of all reported deaths, there is a disproportionate rate of death in children. The rate of drowning is 4.6 per 100,000 per year for children under 5 years of age, three times the rate for adults.[2] In addition, worldwide, drowning episodes are believed to occur around 3–10 times more frequently than drowning.[8–12]

As with the majority of accidental deaths, there is a strong male preponderance with male-to-female incidence ratios ranging from 2 : 1 to 10 : 1.[2,3,6,11] Approximately one in three drowning fatalities occur in accomplished swimmers.[13] Children can and do drown in any receptacle containing water, from buckets to bathtubs to the ocean. The majority of drowning events occur in swimming pools (usually the child's home pool) for children aged under 4 years and in open water for older children.[2,8,14]

Drowning is most frequently a primary event. However, the presence of underlying disease such as epilepsy or cardiac arrhythmia should always be considered along with the possibility of drug or alcohol intoxication in older children. Approximately 6%–10% of drowning victims have a previous history of a seizure disorder,[2,15] and it has been estimated that children with epilepsy have a relative risk for drowning of 96 in the bathtub and 23.4 in a swimming pool compared to nonepileptic subjects.[15] A primary arrhythmia such as prolonged QT syndrome should always be considered, particularly in subjects who are capable swimmers.[16] Approximately 30%–50% of adolescents who drown are intoxicated with drugs or alcohol.[4,14,17]

## Drowning Sequence

Based upon studies in animals,[18] the sequence of events in drowning has been reported as follows:

1. Immediate struggle
2. Suspension of movement with frequent swallowing

3. Violent struggle
4. Convulsions and spasmodic inspiratory efforts
5. Death

Loss of consciousness is thought to be related to hypoxia rather than hypercarbia.[13] Some observers have reported that human victims stop moving suddenly after swimming underwater and then float motionless on the surface of the water and subsequently disappear quietly.[12] The scenario of drowning without a struggle is probably due to a primary loss of consciousness secondary to other factors such as hypothermia[19] or cardiac arrhythmia.[8]

## Sequelae of Submersion/Immersion Events

The drowning sequence has both pulmonary and nonpulmonary sequelae.

### Pulmonary Injury

The majority of drowning victims aspirate water (salt or fresh) at the time of drowning. However, in about 10% of cases, laryngospasm prevents the entry of water into the lungs.[11,20,21] The quantity of fluid aspirated is usually less than 22 mL/kg,[22] a volume that approximates the functional residual capacity (FRC). In cases where aspiration occurs, local insult arises secondary to infection, surfactant depletion, aspiration of debris, and fluid shifts that depend on the relative tonicity of body fluids and aspirated fluid. While radiological pulmonary edema is the most common finding, the incidence and degree appear to be the same irrespective of saltwater or freshwater immersion, although the mechanisms may be different. Seawater aspiration results in an osmotic gradient with fluid shifts into the alveolar spaces,[23–25] whereas aspirated freshwater is rapidly absorbed into the systemic circulation.[26,27] Pulmonary edema may arise in both seawater and freshwater aspiration secondary to neurogenic causes, forced inspiration against a closed glottis, and altered surfactant or pulmonary capillary permeability.[13,28]

Animal data suggests that 0.225% and 0.45% saline solutions are least injurious to the lungs in terms of gas exchange, possibly because they are rapidly absorbed from the alveolar spaces into the circulation along an osmotic gradient.[9,29–31] Freshwater will also be rapidly absorbed but causes rapid inactivation of surfactant and is probably the most injurious fluid to aspirate, followed closely by seawater, which is approximately 3% saline.[9] The presence of chlorine at 1–2 ppm in freshwater (typical of chlorinated domestic pools) does not affect the pulmonary injury.[9]

Although it has been postulated that drowning in hypertonic fluid may lead to hypovolemia secondary to fluid shifts into the alveolar spaces,[24] animal data indicates that hemodynamic changes following drowning are entirely attributable to hypoxia and are independent of the tonicity of the aspirated fluid.[9,29]

Sepsis may occur, including with unusual and or atypical organisms,[32] and significant allergic reactions to aspirated materials have been described.[33] The incidence of pneumonia in adult patients requiring mechanical ventilation, as deduced from a retrospective study in the Netherlands, is around 50%.[34]

Pathological findings are inconsistent and nonspecific. The most common finding in cases where the drowning medium has entered the lungs is the presence of reactive edema, with hyperinflation of the lungs and increase in lung weight *(emphysema acquosum);* however, these findings may also be seen in deaths from other causes including asphyxia and drug overdose.[35] Even where no water has been aspirated into the lungs, neurogenic pulmonary edema can occur.[28]

In severe cases of immersion/submersion accidents (with or without aspiration of fluid), some patients will develop pneumonia and pediatric acute respiratory distress syndrome (PARDS).[36] The management of this disorder is discussed elsewhere in this textbook (see Chapter 38). However, of the patients admitted to the Intensive Care Unit at Children's Hospital Los Angeles over the past 30 years after drowning events, less than 10% developed this serious complication. Figs. 41.1 and 41.2 show the typical radiological course of pulmonary injury in a drowning patient.

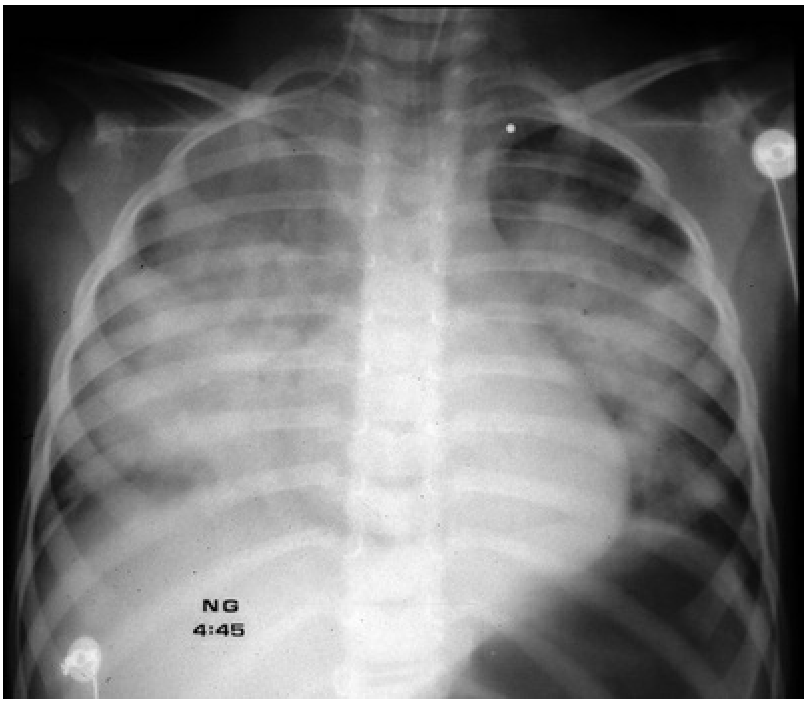

**FIG. 41.1** Initial chest radiograph of a drowning victim. The patient has an endotracheal tube in place and a right subclavian venous line going up into the internal jugular vein. Moderate pulmonary edema and some aspiration pneumonitis are seen, especially on the right.

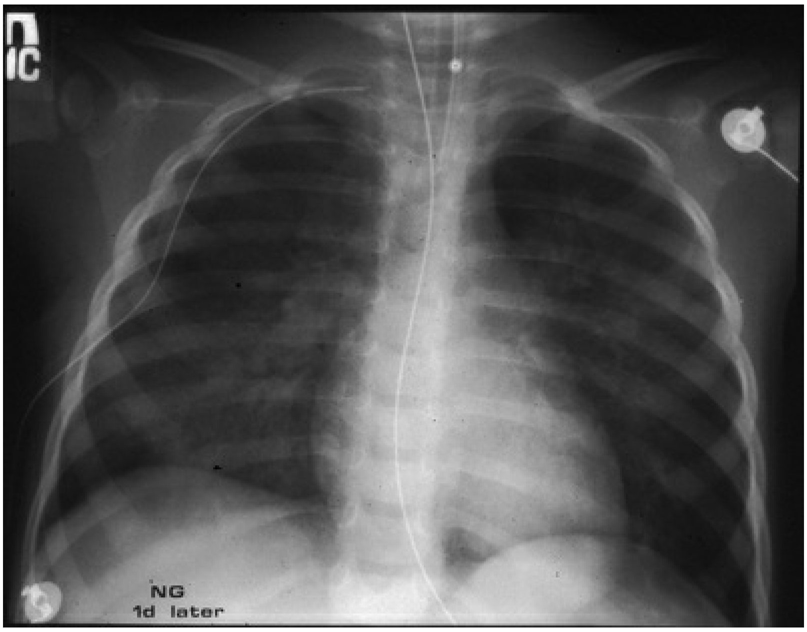

**FIG. 41.2** Chest radiograph of the drowning victim shown in Fig. 41.1 taken 1 day after the event. The patient is still intubated and has a nasogastric tube into

the stomach. The lung fields are almost clear again, but there is a chest tube on the right side that has drained a pneumothorax subsequent to right-sided aspiration pneumonia.

## Nonpulmonary Sequelae

### Hypothermia

Hypothermia is a common manifestation of drowning in water of almost any temperature, and there is anecdotal evidence that rapid hypothermia in a submersion incident is neuroprotective, particularly in children. Conductive losses through the skin are compounded by rapid heat exchange across the pulmonary capillaries if a significant volume of water is inhaled. In a canine model, dogs breathing water at 4°C demonstrated a decrease in carotid artery blood temperature of 8°C within 5 minutes.[19] Cooling occurs most rapidly in small infants who have a relatively large surface area.[37] In cases of extreme hypothermia, rewarming will be essential to allow return of cardiac function.[38,39] Hypothermia can also play a major role in facilitating aspiration in immersion victims. As the core temperature drops below 35°C, muscular incoordination and weakness occur, which can interfere with swimming. As the core temperature decreases further, obtundation develops. At core temperatures below 30°C, unconsciousness can occur and the myocardium becomes irritable. Atrial fibrillation can occur, and at temperatures below 28°C, ventricular fibrillation is likely.

### Electrolyte Imbalances

Electrolyte imbalances may arise if a significant amount of nonisotonic water is aspirated, although this is unusual in regular seawater.[40] Although freshwater immersion victims have decreased serum sodium, and saltwater immersion victims have elevated serum sodium and chloride levels,[20] these are rarely substantial or clinically significant. Even in the Dead Sea, which has electrolyte concentrations approximately 10 times higher than seawater, immersion victims rarely have severe abnormalities of sodium or chloride, although hypercalcemia and hypermagnesemia are common.[41,42] Hemolysis due to aspiration of hypotonic or hypertonic fluids appears to be an extremely infrequent complication.

### Trauma

Traumatic injuries resulting from a fall into water must be considered but are generally of lesser importance than the immersion itself. Cervical spine injuries are the most critical to consider but are uncommon, occurring in only 0.5% of all nonfatal drowning cases, and only then in cases with a clear history of diving, motorized vehicle crash, or fall from a height.[43]

### Hypoxic-Ischemic Damage

All organs are susceptible to hypoxic-ischemic injury following prolonged low cardiac output, and inadequate oxygenation and multiorgan failure is an almost inevitable consequence of severe submersion/immersion injury. Clinically, the brain is particularly susceptible, with the liver and the gastrointestinal tract being the most resistant.

## Management

Management of the pulmonary injury will usually require supplemental oxygen, diuretic administration for pulmonary edema, and the most severe cases will require support with intubation and mechanical ventilation. Many of these serious immersion accidents occur in relatively isolated locales, and often children are intubated in the field or in outside facilities where there may be little experience managing children. Endotracheal tube sizes can be too large and sufficient to cause significant damage to the larynx if not recognized and promptly downsized after arriving at the receiving pediatric institution. In addition, with severe cases, the lung injury will comprise all the features of PARDS. The management of this disorder is addressed in Chapter 38.

Instillation of surfactant has been reported[44–46] and is an appealing therapeutic intervention given that the majority of victims aspirate a quantity of fluid that will denature and wash out existing surfactant. However, the temptation to administer surfactant should be considered in the context of recent randomized controlled trials demonstrating a lack of efficacy of surfactant in PARDS.[47–50] Administration of steroids appears to be effective in animal models of seawater aspiration,[51] and there is evidence to support the use of steroids in PARDS,[52] although this is by no means universally accepted.[53]

Broad-spectrum antibiotics should be administered to treat likely bacterial contamination of the lungs, such as after drowning in stagnant water.[36] The incidence of neurological infection is stated to be high, with a number of case reports in children.[54]

Most drowning victims will be hypothermic at the time of presentation. In cases of extreme hypothermia, rewarming will be essential to allow return of cardiac function,[38,39] and if the core temperature is below 26°C–28°C, or the patient is in cardiac arrest, rewarming is probably best achieved using cardiopulmonary bypass.[55] Given the potential benefits of hypothermia on hypoxic CNS injury, it is our view that modest hypothermia (core temperature 32°C–34°C) should be maintained immediately following the injury until the patient reaches the receiving hospital if there is any suspicion of the patient having sustained a hypoxic brain injury. While duration of submersion, but not water temperature, is reported to be more associated with drowning outcome,[56] excellent neurological outcomes have been reported after prolonged immersion in very cold water, with several case reports indicating full neurological recovery after periods of up to 66 minutes in near-freezing water.[38,57,58] Children lose body heat more rapidly than adults, and if significant brain cooling occurs prior to cessation of circulation, then some degree of neuroprotection may occur. It has been estimated that brain temperature needs to fall by at least 3°C within the first 5 minutes of immersion for cerebral protection to be effective.[37]

The role of induced hypothermia for neuroprotection following drowning remains less certain. Some recent studies have highlighted the beneficial effects of hypothermia on a variety of hypoxic CNS injuries in humans.[59,60] However, these studies had control arms of “usual care,” and some patients became hyperthermic with potential harmful effects and made the hypothermia group outcomes appear better.[61,62] In a Canadian trial using hypothermia in drowned children to reduce intracranial pressure and limit brain injury,[63] the death rate in the hypothermic group was higher than in the normothermic group, with most deaths attributed to neutropenic sepsis. However, this trial was relatively small, and the hypothermia group was also managed with hyperventilation and high-dose phenobarbitone, which may have influenced the outcomes. A randomized, controlled trial of therapeutic hypothermia versus normothermia after cardiac arrest outside of the hospital has been undertaken by 38 pediatric centers in the United States and Canada under the auspices of the National Institutes of Health. This study showed no benefit of hypothermia over rigorously controlled normothermia in either mortality or neurodevelopmentally in the 1-year follow-up of 295 survivors.[64] However, this study excluded patients with cardiac arrest secondary to drowning in ice water who had a core temperature of ≤32°C on presentation. In a subsequent report of the subset of the 74 pediatric cardiac arrest patients due to drowning from this study, it was concluded that hypothermia did not result in a statistically significant benefit in survival with good functional outcome or mortality at 1 year, as compared to normothermia.[65] Current Pediatric Advanced Life Support guidelines no longer recommend consideration of cooling to 32°C–34°C for 12–24 hours in comatose children following cardiac arrest, but support rigorous temperature control to avoid heating.[66]

## Outcome of Pulmonary Injury

Routine tests of pulmonary function have been reported as normal in adults[67] following a drowning accident. However, in a series of 10 functionally normal children[68] studied 6 months to 8.5 years (mean 3.3 years) after the submersion incident, only one had completely normal pulmonary function. Seven had abnormal methacholine challenges demonstrating a high incidence of bronchial hyperreactivity, and five had clear evidence of peripheral airways disease. Whether these abnormalities were related solely to aspiration inherent in the drowning episode or further related to

PARDS was not addressed.[69,70] It is possible these children are at risk for developing chronic lung disease, especially if exposed to further airway or parenchymal irritants.

## Outcome Prediction of Neurological Injury

The best prognostic indicators are observed in the field. The strongest predictor of good outcome is duration of immersion. Poor outcomes are observed in 60%–100% of subjects immersed for greater than 10 minutes, compared to 0%–30% of those immersed for ≤5 minutes.[56] Good outcomes are also associated with the presence of sinus rhythm, reactive pupils, and neurologic responsiveness at the scene.[71] The presence of a detectable heartbeat and hypothermia (<33°C) on arrival to the Emergency Department discriminates intact survivors from those with persistent vegetative state or death.[72,73] Predictors of poor outcome include the presence of cardiac (as opposed to respiratory) arrest and the need for prolonged resuscitation (more than 20–25 minutes) or the requirement for more than two doses of epinephrine.[72–74]

The prediction of the neurologic outcome of those children who survive the initial resuscitation event and arrive in the intensive care unit in a comatose state is highly relevant for parents and caregivers. It is difficult to provide early and accurate prognostic information on comatose children, especially if brainstem functions are intact. Severity of illness scores such as the Pediatric Index of Mortality (PIM) and Pediatric Risk of Mortality (PRISM) scores were developed to predict the risk of death in groups of patients and not individuals. However, PRISM has recently been applied to individuals, and it enables the prediction of either absence or presence of serious neurological impairment or death in pediatric drowning patients if they present at extreme values on this scale. In patients with intermediate PRISM scores, though, it is not possible to establish a reliable prognosis.[75] Electrophysiological investigations, such as brainstem auditory evoked potentials and short-latency somatosensory evoked potentials (SSEP), are helpful to assess the likelihood of a permanent vegetative state or a higher level of cognition. The bilateral absence of SSEP is an established predictor for a worse clinical outcome after cerebral hypoxia.[76,77]

Diffusion-weighted magnetic resonance imaging (DWI) provides a quick and reliable tool to detect early tissue injury in acute cerebral ischemia, because it is sensitive to water shifts between the extracellular and intracellular compartments, which conventional MRI often cannot detect. Preliminary results suggest that the extent of diffusion-weighted MRI pathology may serve as a reliable predictor for neurological outcome after cerebral hypoxia (Fig. 41.3).[78] Magnetic resonance spectroscopy also shows promise as a diagnostic and prognostic tool in hypoxic/ischemic cerebral injury, with reduced N-acetyl aspartate (NA) and elevated lactate both associated with poor neurological outcomes (Fig. 41.4).[79,80] Although computed tomography (CT) is not a sensitive test for ischemic injury, the presence of any CT abnormalities suggestive of ischemia (typically loss of gray-white differentiation and/or basal ganglia edema or infarction) within the first 3 days of drowning is strongly correlated with poor neurological outcome, and the presence of CT abnormalities in the first 24 hours is associated with a very high risk of mortality.[81]

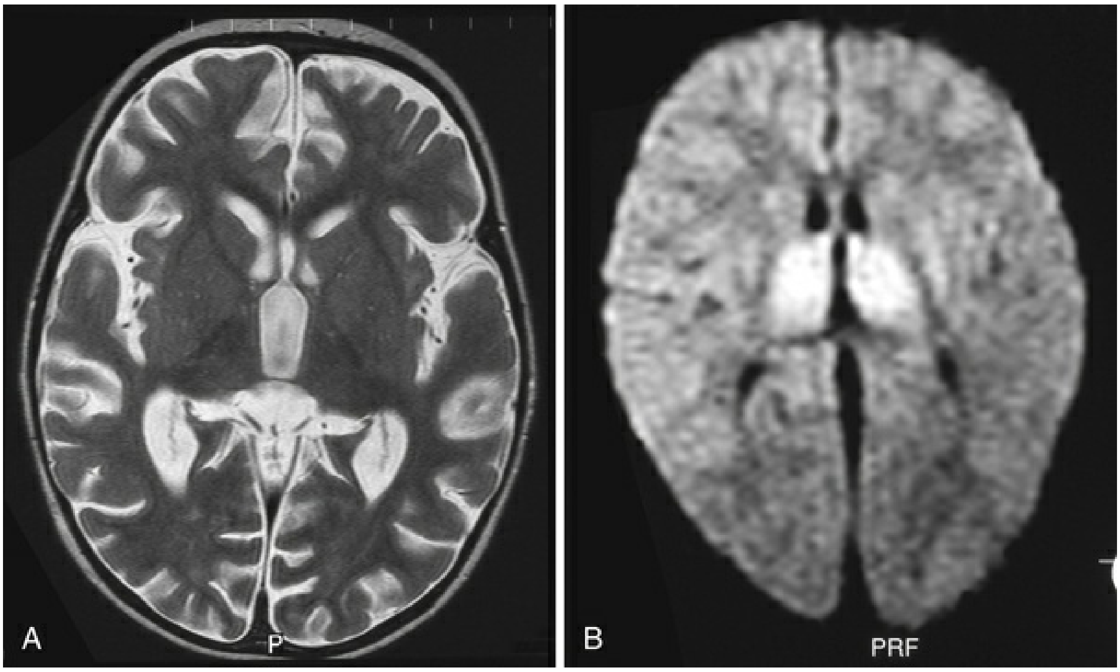

**FIG. 41.3** Magnetic resonance imaging (MRI) of the brain of a 3-year-old child 36 hours after a drowning accident. The child remained in a persistent vegetative state. (A) The T2-weighted conventional MRI revealed no signs of hypoxia. (B) Diffusion-weighted imaging

shows hyperintensity bilaterally in the basal ganglia.

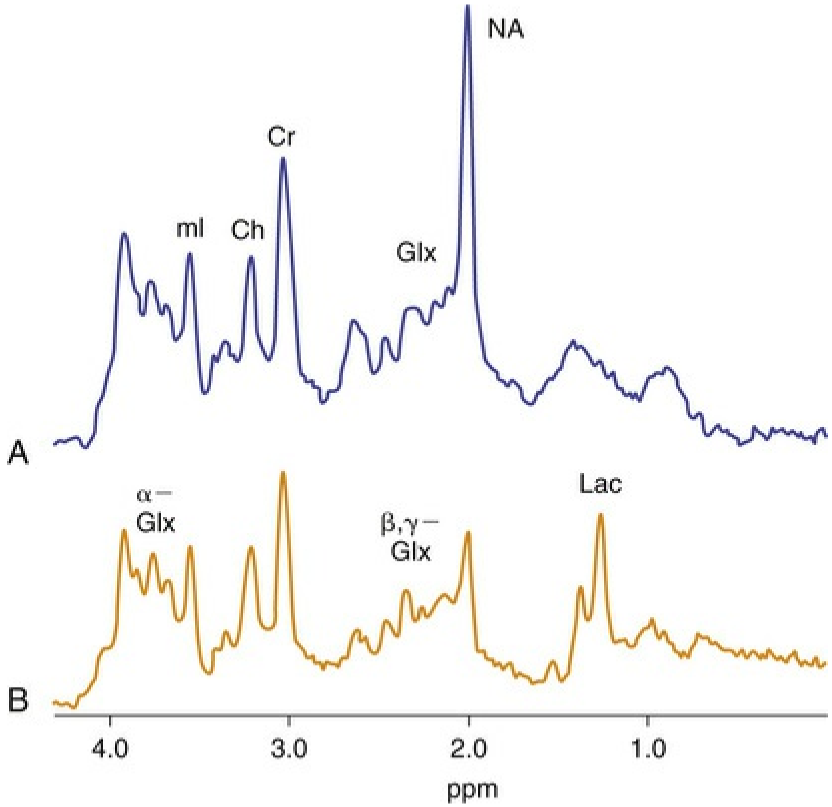

**FIG. 41.4** Cerebral ${}^1$H-MR spectra of occipital GM in a 3-year-old boy 48 hours after a severe immersion injury (B) compared with a control spectrum of a healthy age-matched subject (male, 4 years) in (A). The spectrum of the patient who died 70 hours after injury is characterized by a dramatic loss of NA (2.0, 2.6 ppm), a decrease in Cr (3.0 and 3.9 ppm), a large increase in Lac (1.3 ppm), and change in the resonances of Glu and Gln (3.75, 2.0–2.5 ppm). (From Kreis R, Arcinue E, Ernst T, Shonk TK, Flores R, Ross BD. Hypoxic encephalopathy after drowning studied by quantitative 1H-magnetic resonance spectroscopy. *J Clin Invest*. 1996;97:1145.)

## Prevention

Drowning disproportionately affects children, and the majority are preventable. Drowning causes significant mortality and morbidity throughout the world, although modest decreases in the overall rates have been reported recently in the United States.[82] Factors that appear to have reduced the number of those drowned each year are legislative and public health interventions such as pool fencing and public education campaigns that have improved awareness of the dangers of leaving children unattended in bathtubs and of large commercial-type buckets into which smaller children can fall but not extricate themselves (Fig. 41.5). Participation in formal swimming lessons has been demonstrated to be an effective preventative strategy in younger (1–4 years old) but not older children.[83] So far, improvements in postresuscitation care have not been shown to alter outcome significantly if there has been an out-of-hospital cardiac arrest.

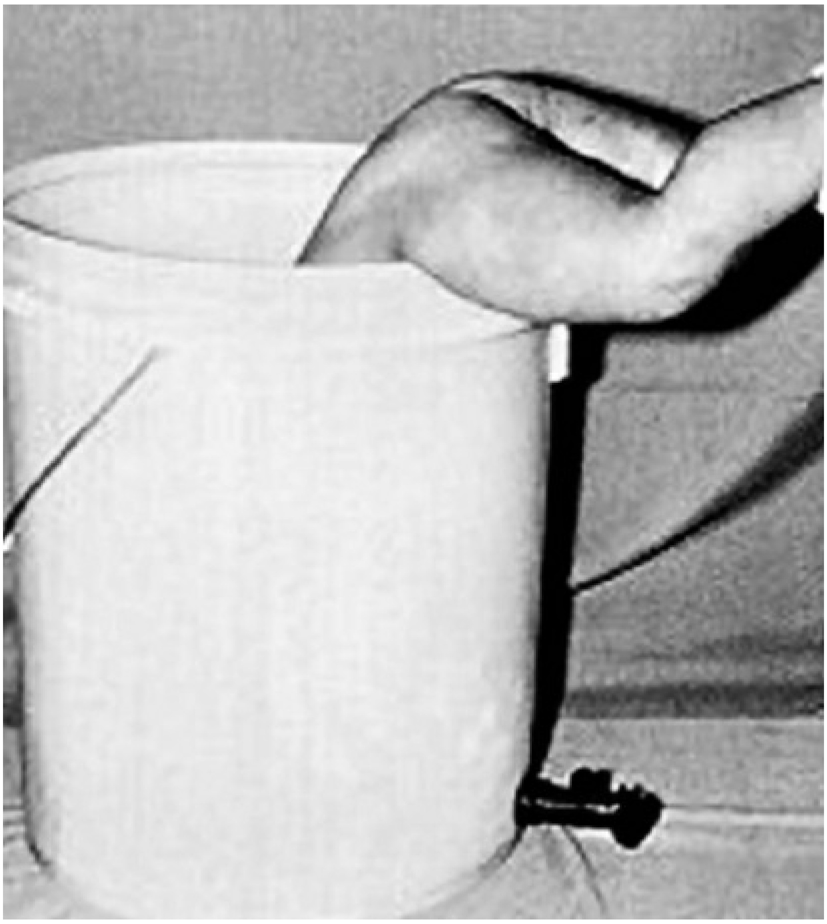

**FIG. 41.5** The body of a small child who had tipped headfirst into a bucket of water. The upper segment (torso and head) of a child is longer and heavier than the lower segment (unlike an older child or adult), and he could not extract himself. (From Moon RE, Long RJ. Drowning and near-drowning. *Emerg Med*. 2002;14:378.)

# The Epidemiology of Asthma

*Alexander John Henderson MD, FRCP, FRCPCH, FRCPEd*

## Overview

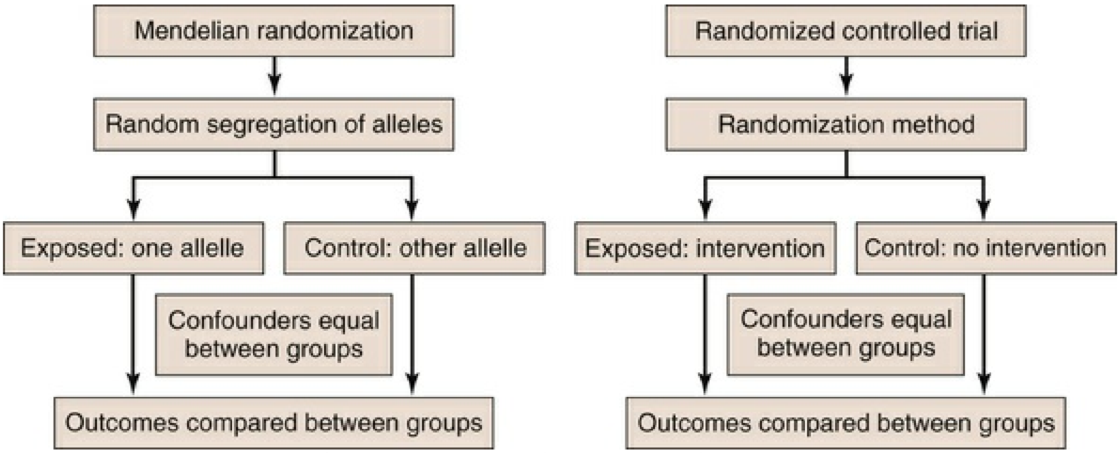
Asthma is one of the most common noncommunicable chronic diseases of childhood. It creates a major public health and economic burden on society through its impact on mortality, morbidity, lost school days for children, lost workdays for parents, quality of life (QoL), and costs of health care. Epidemiologic studies have tracked changes in asthma prevalence across time and place and have provided insights into some of the environmental influences that might influence asthma onset, severity, persistence, and outcome. Longitudinal cohort studies have pointed to early life factors, including genetic predisposition, as being critically important in the development of asthma; however, its cause remains elusive. Recent advances in understanding the genetics of asthma and the application of more robust causal epidemiologic models to the consideration of modifiable exposures associated with asthma onset and natural history have started to get around some of the traditional problems of bias and confounding in epidemiology that hamper the identification of the true causes of disease. This chapter will review asthma epidemiology with particular emphasis on how technological and methodological progress can help unlock the potential of the considerable recent growth of asthma epidemiologic studies around the world.

## Epidemiologic Approaches to the Study of Asthma

The goal of epidemiology is to identify modifiable factors that influence disease in populations, thus leading to interventions that will prevent disease from occurring or alter its natural history, either by cure or other reduction in the burden of disease. There are several different study designs that have been used in epidemiology to achieve these aims, of which the randomized control trial (RCT) provides the highest level of evidence for a causal relationship between a risk factor and the disease outcome. This is because covariables associated with the risk factor of interest could themselves influence the disease outcome; for example, many environmental exposures are strongly socially patterned and therefore associated with other variables that are influenced by socioeconomic factors. An illustration of this is that people who work in low-income jobs tend to live in disadvantaged, urban areas where they are exposed to poor housing conditions (damp, molds) and more traffic-related pollution, and their lifestyles are more likely to include higher tobacco and alcohol consumption and less physical exercise. Therefore, in a well-designed RCT where subjects are randomly assigned to an intervention ("risk" factor) or comparison (control) group, their additional environmental and lifestyle factors will also be randomly assorted between the intervention and comparison groups. This means that it can be reasonably inferred that any differences in outcome between the two groups is due solely to the intervention being studied.

In all other conventional epidemiologic study designs, these factors remain as possible explanatory variables that confound the relationship between exposure and outcome. A cross-sectional study samples a population at a point in time, collecting information on exposures and outcomes contemporaneously. It is a relatively quick and resource-effective study design, but suffers from uncertainty about the direction of associations between risk factors and disease. (Did A cause B or did B cause A, or did an unknown C cause both?) A case-control study recruits established cases of disease and draws comparable subjects from a suitable source, such as health care settings, electoral rolls, etc. Exposure history is ascertained retrospectively and therefore subject to problems of recall; differential recall of exposure between cases and controls will introduce bias. This design can consider many different exposures for the disease of interest and is relatively quick to perform as the outcome is already known. The other major study design for epidemiologic purposes is the cohort study, which follows a population sample that is disease-free at recruitment to ascertain disease outcome after a period of time. Exposures are ascertained prospectively so the direction of association between exposure and outcome can usually be reasonably inferred. A particular type of cohort study, the birth cohort in which infants are recruited at birth and followed for many years, has been instrumental in shaping our understanding of the evolution of asthma during childhood and the exposures in early life, including before birth, that influence the onset and the natural history of asthma throughout childhood and beyond. Although it is helpful to establish temporal associations between exposure and disease, as with all study designs the sources of bias and error need to be minimized. A particular issue with cohort studies is loss to follow-up of the initial sample. Where a factor, such as continued participation in a cohort study or recruitment of a clinic sample, is affected by exposure status and outcome, conditioning analysis on this factor, for example, complete-case analysis, can introduce spurious (noncausal) associations between the two variables on which it depends, a form of collider bias described by Berkson[1] and referred to as Berkson bias or paradox. Another variation of the cohort design is an historical cohort study, where an exposure has been measured previously in a disease-free population and that population is contacted at a later date so that outcomes can be ascertained. A good example of this comes from historical records of birth weight in a population of adult males that were traced, and in whom cardiovascular and respiratory outcomes were measured in old age. These showed strong associations between low birth weight and increased risk of cardiovascular disease, low lung function and chronic obstructive pulmonary disease (COPD) and were instrumental in formulating the concept of the developmental origins hypothesis of health and disease throughout the life course.[2] Finally, an ecological study can be conducted by ascribing exposures and/or outcomes to groups of individuals defined geographically, for example, by country of residence, or temporally. Exposures and outcomes are averaged across populations and thus cannot be ascribed to individuals within these population groups.

Confounders can be taken into account in analyses that control for their influence, but it is seldom the case that all possible confounders can be accounted for, either because they were not measured or in some cases could not be measured, giving rise to residual confounding. One of the difficulties of investigating asthma epidemiology is the huge range of potential explanatory variables that might influence population disease risk, and, hence, confound the associations between risk factors and asthma outcomes. A further complication is the heterogeneity of asthma, which varies in several domains, such as age of onset, frequency and severity of symptoms, response to treatment, association with allergy, and natural history over the life course of the individual. It is conceivable that different types of asthma manifest as phenotypic variation *(phenotypes)* underpinned by variation in biological pathways *(endotypes)* that may, in turn, be influenced by different risk factors. If this is the case, modest associations between risk factors and asthma in a population may mask large effects in a subpopulation with a specific phenotype. An example of this might occur with occupational exposures, such as wheat flour causing “baker's” asthma, which applies to only a limited proportion of a population and results in a specific type of asthma that could be missed without a proper occupational history and its temporal relationship to symptoms. In this instance, modification of the risk factor will likely have no detectable benefit in the population unless it is restricted to those with the risk phenotype. The problem of residual confounding has beset observational epidemiology from its outset and, although criteria have been developed to help strengthen the evidence for casualty, there are many examples in the literature of strong epidemiologic associations that were not confirmed by RCT evidence; indeed, in some cases, associations were discovered to be in the opposite direction. Technological advances that are applicable to population studies enabling large-scale genotyping have led to the discovery of genetic variants (single nucleotide polymorphisms [SNPs]) that influence exposures that themselves may be risk factors for disease, for example, birth weight and smoking behavior. Because genotype is randomly allocated at meiosis, a situation analogous to the RCT can be constructed (with certain constraints) using genetic instruments as an unconfounded proxy for exposure in the mendelian randomization design (Fig. 42.1).[3] As genetic knowledge increases, it is hoped that this approach will allow better inference of casual relationships between exposures and asthma, thus enabling targeting of intervention studies to variables that have stronger prior evidence of causing disease.



Mendelian randomization
Random segregation of alleles
Exposed: one allele
Control: other allelle
Confounders equal between groups
Outcomes compared between groups
Randomized controlled trial
Randomization method
Exposed: intervention
Control: no intervention
Confounders equal between groups
Outcomes compared between groups

**FIG. 42.1** Comparison of design of Mendelian randomization studies and randomized controlled trials. (From Davey Smith G, Ibrahim S. What can Mendelian randomisation tell us about modifiable behavioural and environmental exposures? *BMJ*. 2005;330:1076. doi:10.1136/bmj.330.7499.)

## Defining Asthma in Epidemiologic Studies

To the majority of clinicians, the diagnosis of asthma appears to be relatively straightforward. A combination of a clinical history of the cardinal symptoms of cough, wheeze, and breathlessness varying over time and associated with identifiable triggers supplemented by measures of airflow obstruction that varies spontaneously or in response to short-acting bronchodilators provides a high prior probability of asthma in children. National and international evidence-based guidelines have been developed to assist pediatricians and primary care physicians in making a diagnosis of asthma and directing its management: http://www.nhlbi.nih.gov/health-pro/guidelines/current/asthma-guidelines; https://www.brit-thoracic.org.uk/guidelines-and-quality-standards/asthma-guideline/; http://ginasthma.org/.

Of course, although the diagnosis of asthma is often straightforward and treatment effective, there are exceptions when the diagnosis is in doubt, particularly in infants and preschool children, or treatment does not produce the expected reduction in symptoms. Great efforts have been made to avoid underdiagnosis and undertreatment of asthma, which was a perceived problem in the past, but recent concerns have been raised in high-income countries (HICs) that asthma may now be overdiagnosed in some settings, highlighting some of the uncertainties that remain in clinical recognition of the condition. The continued recognition of avoidable asthma deaths in children, however, emphasizes the importance of maintaining a balance that appropriately recognizes and treats children at risk. In epidemiologic studies, which are carried out at population rather than individual level, it is usually impracticable to clinically examine every participant to identify cases of asthma, so different methods need to be employed. The most frequently used of these has been the written asthma questionnaire, which is designed to be self-completed or parent-completed in young children. This evolved from the Medical Research Council (MRC)[4] and International Union against Tuberculosis and Lung Disease (IUTLD)[5] respiratory questionnaires, and has been standardized for use across different countries and cultural settings by the International Study of Asthma and Allergies in Children (ISAAC) survey (http://isaac.auckland.ac.nz/) and is now the most commonly reported method of defining asthma in epidemiologic studies. Concerns have been expressed that parental understanding of the term “wheezing” could lead to bias and misclassification in estimates of asthma prevalence based on questionnaire surveys. Parents' perception of wheezing has been found to be imprecise compared with clinical findings,[6] different wording of questionnaires can affect prevalence estimates,[7] and clinician-confirmed compared with parent-only reported wheezing was associated with measured airway obstruction in young children,[8] suggesting misclassification of asthma in the latter group. Understanding of the term "wheeze" may also differ between ethnic groups, leading to overestimation or underestimation of its prevalence. The development of a video questionnaire for adolescent children by the ISAAC team (http://isaac.auckland.ac.nz/phases/phasethree/videoquestionnaire.h sought to address the linguistic and sociocultural differences in questionnaire interpretation. This has been validated against bronchial hyperresponsiveness (BHR) in a number of settings with some variation but generally satisfactory agreement. Comparison of the video with the written questionnaire suggests that their agreement is moderate, although the latter may underestimate the prevalence of asthma symptoms in 10- to 12-year-olds.[9] In contrast, an earlier study in a different setting, while suggesting generally good agreement in 13- to 14-year-olds reported that the video questionnaire identified fewer cases than the written questionnaire.[10] A UK cohort study linked responses to asthma questionnaires in a longitudinal birth cohort to primary care diagnoses in electronic patient records and reported that questions about wheezing had high sensitivity but low specificity for a diagnosis of asthma, and BHR was only found in 50% with a primary care diagnosis.[11] Therefore, it is important to be aware of the possible sources of error and bias in epidemiologic estimates of asthma prevalence, particularly when comparing changes over time, or variations across different study settings. It is equally important to recognize that a population of children with asthma identified through an epidemiologic survey will differ from a clinic population, usually through the inclusion of a greater proportion with less severe asthma, and with a greater chance of misclassification, whatever methods are used. Supplementing responses to a written questionnaire with an objective test, such as bronchial responsiveness to a chemical or physical challenge, is likely to increase specificity but reduce sensitivity of identifying asthma cases.

# The Prevalence of Asthma

The prevalence of asthma varies by time, place, and person (population). Asthma is generally accepted to occur as a consequence of genetic factors interacting with the environment and lifestyle of an individual, perhaps at critical stages of development. By studying variations of prevalence across the domains of time, place, and person, it is possible to gain insight into the factors influencing asthma in different settings and thereby discover important risk factors for the disease.

## Temporal Variation

Following a well-documented epidemic of asthma deaths reported in children and young adults (5–34 years) in several, but not all, industrialized HICs in the 1960s, Burr reported an increase in asthma hospital discharges of 5- to 14-year-old children in Wales. This prompted a series of cross-sectional surveys at intervals, which demonstrated a doubling in the prevalence of ever having asthma in children in South Wales from 6% in 1973 to 12% in 1988; 15 years later. A similar trend was seen in 6–11-year-old children in the US National Health and Nutrition Examination Survey (NHANES) between the early and late 1970s, and in a number of other countries over a comparable epoch from the early 1970s through the 1990s, including the UK, Scandinavia, Israel, New Zealand, and Australia. These mainly relied on parental report of wheeze and/or asthma in repeat cross-sectional surveys of parents in the same geographical setting. By 2000, there were indications that the rising prevalence in childhood asthma in high-income, developed countries was coming to an end. A Swiss study based on national surveillance data suggested that this reversal of the previous trend could be explained by fewer consultations for allergic asthma.[12] One of the longest running surveys of asthma and allergy symptoms started in Aberdeen, UK, in 1964, and has used the same methods in repeat studies of the same age group of children in an economically stable environment with low levels of migration in studies spanning a 50-year period. The original surveys showed contemporaneous rises in the prevalence of asthma, eczema, and rhinitis in this age group of children, pointing to a common etiology mediated through influences on allergic mechanisms. However, later studies, which confirmed a “flattening” of the previous trend for increased prevalence of these conditions similar in magnitude and direction to results from comparable HICs, showed a continued rise in the lifetime prevalence of eczema and hay fever, thus throwing doubt on a common etiology of these conditions.[13] Therefore, the summation of evidence, largely from repeat surveys using identical methodology in different settings, suggests that reported asthma prevalence and the prevalence of asthma symptoms showed an increase from the early 1990s until around the end of the 20th century. However, there are a number of considerations that need to be taken into account before accepting this as evidence for a true increase in disease prevalence. These include changes over time in diagnostic coding, such as changes in the International Classification of Diseases (ICD) definitions; diagnostic preference, such that wheezing illnesses may or may not be labeled as asthma; increased population awareness leading to more presentations to health care with asthmalike symptoms; and systematic bias in questionnaire responses. Although repeat surveys were carried out in comparable groups from similar strata of society, they were not the same individuals or families, so they may have differed in their responses without there being a true change in symptoms. Subsequent analyses have suggested a diagnostic shift explaining part of the observed increase in prevalence, but there is still evidence that at least part of the rise in asthma prevalence was real. The ISAAC study has provided a global perspective of these changes in symptoms over time through incorporation of a repeat survey in the third phase of the study (ISAAC phase III), which was designed to describe time trends and factors associated with these in the centers that completed phase I, which established baseline estimates and their geographical variation. Phase III followed the initial phase by at least 5 years with an average interval of 7 years. The study gathered data from over 190,000 6- to 7-year-olds in 37 countries and over 300,000 13- to

14-year-olds in 56 countries. These showed that between 1992 and 1998, and 1999 and 2004, centers were about equally distributed between substantial increases and decreases in the prevalence of asthma symptoms, whereas in 6- to 7-year-olds more centers showed an increase than a decrease in prevalence (Fig. 42.2). Analysis of the relationship of time trends between asthma, eczema, and rhinitis showed that the strongest correlation was between eczema and rhinoconjunctivitis, and the weakest between eczema and asthma. However, the relationships overall showed consistency across the study period, suggesting that similar factors are affecting them at a global level,[14] and there was no strong association with gross national income across the low-income countries to HICs comprising the study centers, despite differences in the proportion of atopic and nonatopic asthma between high- and low-to-middle income countries; nonatopic asthma is more prevalent in the latter.[15]

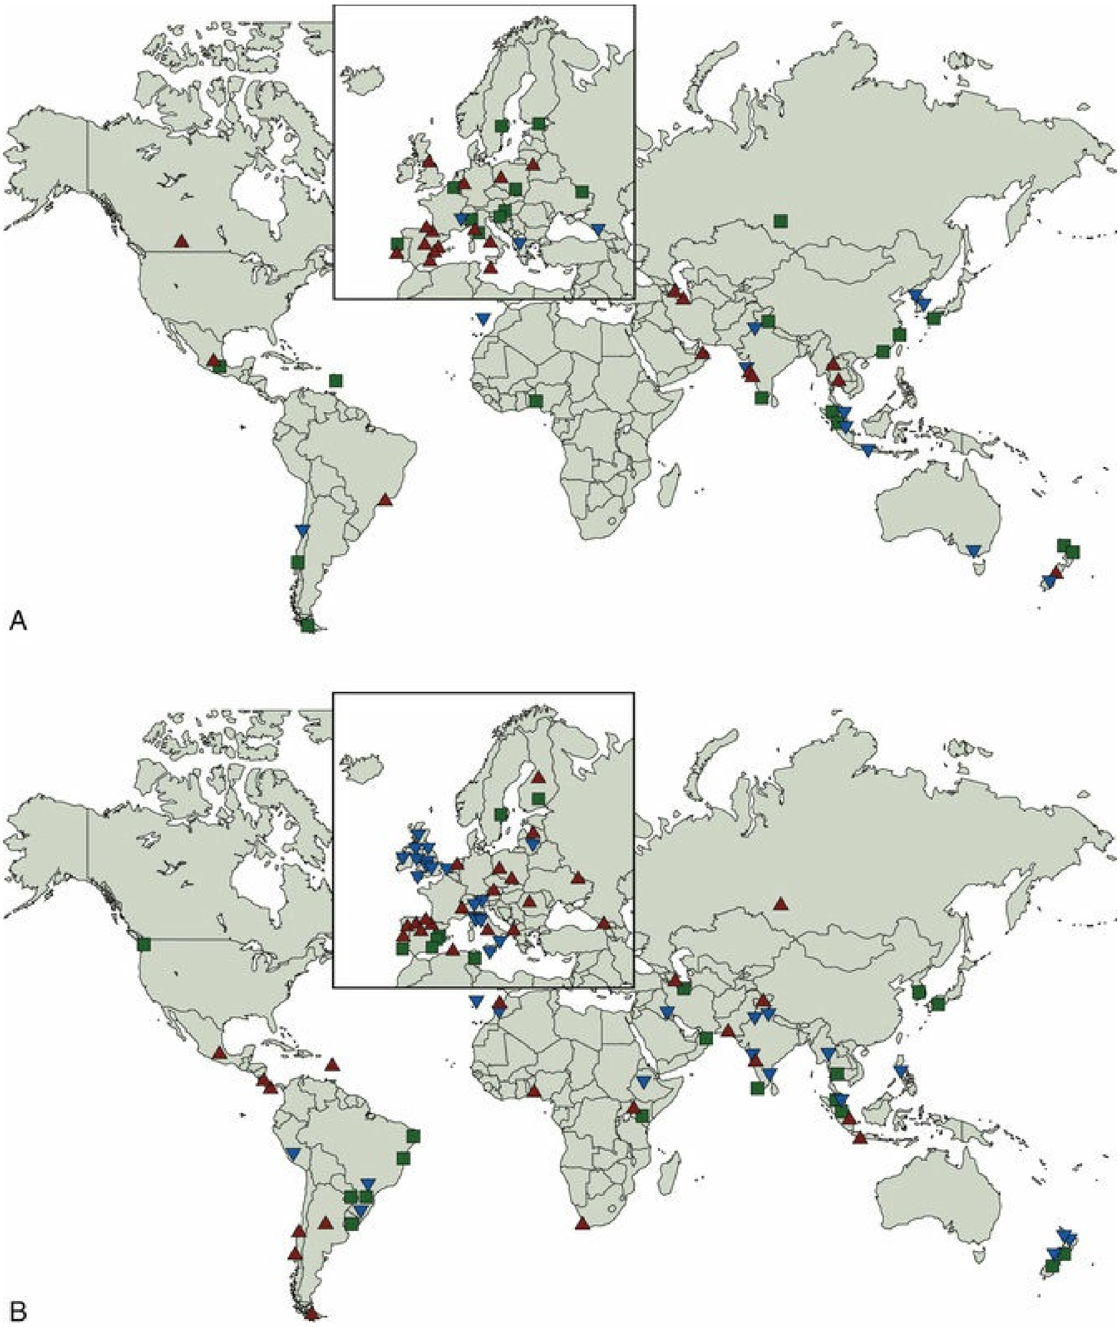


**FIG. 42.2** World map showing the direction of change in the prevalence of asthma symptoms for the 6- to 7-year age group (A) and 13- to 14-year age group (B). Each symbol represents a center. *Blue triangle* = prevalence reduced by ≥1 Standard Error per year. *Green square* = little change (<1 Standard Error). *Red triangle* = prevalence increased by ≥ 1 Standard Error per year. (From Asher MI, Montefort S, Björkstén B; ISAAC Phase Three Study Group. Worldwide time trends in the prevalence of symptoms of asthma, allergic rhinoconjunctivitis, and eczema in childhood: ISAAC Phases One and Three repeat multicountry cross-sectional surveys. *Lancet*. 2006;368(9537):733-743.)

To address the question of whether reported increases in the prevalence of reported symptoms of asthma represent a true underlying change in disease incidence and/or natural history, it is instructive to consider other markers of disease activity that may indicate whether the figures reflect a change across all grades of asthma severity or the inclusion of a greater proportion of milder disease; the latter could represent diagnostic shift to include milder cases or a true change in asthma severity or its management. For example, better drug treatments or behavioral shifts leading to greater adherence to asthma medication, could impact health care utilization without affecting the underlying disease prevalence. Similarly, changes in health care organization over time, such as greater emphasis on emergency room care, could reduce hospital admission rates without changes in asthma attack rates, perhaps due to direct discharge of more moderate cases. Surveillance data from the United States has confirmed a 4.6% annual increase in asthma 12-month prevalence in children (<17 years) from 1980 through 1995 with a stabilization of current asthma prevalence since 1997.[16] Asthma-related emergency department visits remained relatively stable between 1992–2006 while asthma deaths in US children increased by 3.2% per year from1980 through 1996 and have since decreased. These data are broadly supported by similar trends in the UK[17]; children (<14 years) had increased reported prevalence of asthma symptoms and about an eight-fold increase in primary care consultations for asthma between the 1970s and mid-1990s. This was accompanied by increased hospital admissions for asthma until 1990, since when they declined (Fig. 42.3). The evidence of increased prevalence of asthma of all grades of severity during the last few decades of the 20th century support a true increase in disease prevalence rather than a broadening of disease classification.

## Spatial Variation

The potential of investigating spatial or geographical variations in asthma was exemplified by the landmark studies in Germany following its reunification in 1990. The distinct advantages of this setting were the shared genetic ancestry of the populations of East and West Germany coupled with the contrasting lifestyles and environments of the German Democratic Republic in the East and the Federal Republic of Germany in the West. Thus, it was possible to investigate different environmental influences in two genetically similar groups. At the time, the contemporaneous increase of asthma prevalence in the West and the marked increases in road traffic densities had indicated traffic-related pollution as a possible contributor to asthma etiology. It was reported that the prevalence of atopic sensitization, hay fever, and asthma was higher in children born in the West, where traffic-related pollution dominated, whereas bronchitis prevalence was higher in the East, where industrial sources of pollution persisted.[18] The first phase of the ISAAC study mapped the prevalence of asthma in 6- to 7- and 13- to 14-year-old children using comparable survey methodology, and showed the highest prevalence in countries where English was the first language and which could be described broadly as having a “Westernized” lifestyle, and in Latin America. However, some of the regions with the highest reported levels of air pollution had generally low asthma prevalence, pointing away from air pollution as a major cause of asthma onset (as opposed to exacerbations). The follow-up phase 3 ISAAC report continued to show striking variation in asthma prevalence (http://isaac.auckland.ac.nz/story/methods/maps.php#mapMenu) between countries with similar regional patterns to the phase 1 study published 11 years earlier, and was mirrored by the prevalence of symptoms of severe asthma; high prevalence was associated with HICs. Intercountry comparisons of asthma prevalence present an opportunity for ecological analyses of the differences in lifestyles and exposures associated with asthma in these settings. Although such approaches can give clues about possible etiologic factors, population genetic differences could influence the environmental exposures that are instrumental in asthma onset in different populations. This is particularly important in the study of complex, polygenic diseases, such as asthma, that arise from interactions between genes and environment. However, because the confounders of associations between risk factors and asthma almost certainly differ between regions, an opportunity is presented to strengthen causal inference of exposure-outcome links. If associations between a putative risk factor and asthma are replicated in settings with markedly different lifestyles and environments, it is likely that confounding plays a lesser role in explaining such relationships, making the risk factor the more probable (causal) explanation.

One key difference between countries with contrasting asthma prevalence in the ISAAC studies is the degree of urbanization. An attempt has been made to address this question using satellite images to estimate the extent of urban development and matching these to ISAAC study centers.[19] Despite some, but not all, regional studies, mostly set in low-income countries, reporting links between increased urbanization and asthma prevalence, this global perspective showed only weak evidence of any association between urban development and asthma prevalence, including severe asthma symptoms, in children. Considering asthma prevalence in HICs, there is clear evidence from the United States that asthma prevalence is higher in urban areas with a high proportion of ethnic minority populations, and this is reflected in higher indicators of morbidity and mortality in children of Hispanic and African-American origin. Many possible explanatory factors for this observation have been suggested, including genetic predisposition and environmental exposures associated with social disadvantage, such as outdoor and indoor air pollution, allergens, infectious agents, and diet. These will be considered further under etiologic factors associated with asthma. A further ecologic association arising from the ISAAC studies is the low prevalence of reported asthma in countries where a high proportion of the population lives in rural areas with reliance on subsistence farming. These observations are consonant with studies from rural communities, mainly in middle Europe, but replicated in other settings, where the prevalence of asthma and allergy has been reported to be lower in children growing up on farms and exposed to livestock and other factors, such as drinking unpasteurized milk. The common mediating factor of this protective effect is now believed to be early life exposure to microorganisms and their cellular constituents, including endotoxins. Higher levels of endotoxin in dust collected from farms has been associated with lower prevalence of sensitization and allergic diseases, although later exposure from household dust can exacerbate asthma symptoms in urban settings.[20,21] Recent evidence suggests that the protective effect of endotoxin exposure in early life is mediated through induction of an enzyme (A20) in the pulmonary epithelium that modifies interactions between the epithelium,[22] antigen-presenting cells, and the innate immune system.[23]

Of particular interest in the geophysical variation of asthma prevalence is the effect of migration between settings with widely varying rates of asthma. Migrants from countries with low asthma prevalence to high prevalence countries have acquired the rates of asthma in the local population, with the effect dependent on the time spent in the adopted country. There is also evidence that the younger age at which migration occurred in these circumstances, the higher the prevalence of later asthma, lending support to the early origins hypothesis that environment in infancy and early childhood is critical for the development of diseases through the life course. The ISAAC study group has recently analyzed data on migration and reported that being born outside the country of study was associated with a lower prevalence of asthma in both 6- to 7- and 13- to 14-year-old children. This protective effect was restricted to affluent countries and was not evident in low-income settings with low asthma prevalence. It was also lost with increasing time spent in the host country, and points to environmental factors as opposed to genetic factors being important in the variation of the prevalence of asthma between countries.[24,25]

## Variation by Gender and Ethnicity

Asthma prevalence is disproportionately higher in black and ethnic minority populations than in white children of European ancestry. The explanations for such disparities are likely to be multifactorial and include genetic and environmental influences, urban living, poverty, and access to health care.[26] Although asthma has high heritability, racial and ethnic minorities are underrepresented in genetic studies of asthma (see: http://www.ebi.ac.uk/gwas/home for a catalog of genome wide association studies [GWAS]) and the current commercially available chips for genome wide, SNP screens were derived from populations of mainly European descent. In Southern California, a study using genetic markers of ancestry in Hispanic children showed that those with a lower proportion of African ancestry were at a lower risk for asthma than those who had major contributions from European or Amerindian ancestries.[27] In common with many other developed, Anglophone countries, asthma prevalence in children in the United States approximately doubled from the early 1980s until the late 1990s. At the beginning of this period, there was little disparity between white and black children, whereas by 2010, the prevalence in African-American children was twice that of their white peers.[28] During the period from 2000 onwards, when the previous increase in asthma prevalence in US children has plateaued, the disparity between asthma in black and white children also stopped increasing. This was largely due to a slowdown in the increasing prevalence of non-Hispanic black children, although asthma prevalence in some groups continued to rise, including those from a deprived socioeconomic background.[29] In addition to higher asthma prevalence, African-American and Hispanic children in the United States were reported previously to have increased rates of hospitalization, emergency department use, and mortality due to asthma than their white counterparts, although a national analysis of in-patient data has reported increased mortality only for Native American children and not for other racial or ethnic groups.[30] In the same study, the length of hospital stay after admission for an asthma attack was related to indicators of social deprivation but was shorter in Asian than in white children. In the UK Leicester Respiratory cohort, which has a high proportion of South Asian participants, a higher prevalence of ever having wheezed was reported in Asian compared with white children, but current symptoms of wheeze and night cough at age 6 years were similar between the two groups.[7] In this study, associations with risk factors were also similar between white and South Asian children. Others have reported racial disparities in some associations, including body mass index (BMI), which was more strongly associated with asthma in US children who were male, non-Hispanic black, and living in deprived neighborhoods,[31] traffic-related air pollution (TRAP), which was associated with hospital readmission in white but not African-American children,[32] and possibly airway inflammatory responses to environmental tobacco smoke (ETS) in adolescents.[33] Intriguingly, racial differences in treatment responses in severe, therapy-resistant asthma have been reported, with poorer fractional exhaled nitric oxide (FeNO) responses in black than white children to intramuscular steroid injections.[34] The mechanism of this has yet to be discovered, although differences in genes affecting pharmacologic responses are likely to be important and could pave the way to personalized approaches to treatment.[35]

Asthma is more common in males in early childhood but a gender switch in asthma prevalence occurs around the time of puberty, so asthma prevalence in young adults is higher in females than males; although reporting bias in favor of asthma in young males has been suggested to explain at least part of the apparent gender switch.[36] The ISAAC study reported a higher prevalence of asthma in males at 6–7 years and a higher prevalence in females at 13–14 years with considerable variation between centers. In the UK longitudinal Isle of Wight cohort, males had a higher prevalence of asthma up to 10 years, which had reversed to higher female prevalence by 18 years, with more wheezing females gaining an asthma diagnosis between 10 and 18 years.[37] Some cross-sectional studies have suggested that the sex discordance in asthma observed through the peripubertal period has become less exaggerated in recent years. There is some uncertainty about the precise age at which the gender switch occurs and its relation to the onset and timing of puberty. Symptom severity has been reported to be greater in boys in early childhood, transitioning through 7–9 years to be greater in females from 10 to 17 years, with a marked influence of puberty on symptom progression.[38] Early menarche in girls has been associated with an increased risk of incident asthma.[39,40] These observations have implicated estrogenic effects as potential mediators of the increased prevalence and severity of asthma in females around the time of puberty. Estrogen receptors are expressed on many cell types, including airway smooth muscle. Their expression in immune cell lines is associated with enhancement of allergic inflammation through Th2 skewing of immune responses, isotype switching of B cells to immunoglobulin E (IgE) production and mast cell degranulation. On the other hand, some evidence points away from estrogenic effects, such as fluctuations in bronchial responsiveness through the menstrual cycle being associated with alterations in serum testosterone concentrations, and it is probable that multiple factors, including sex differences in biological and lifestyle variables, are associated with the changes in asthma prevalence that occur during transition to early adulthood.

## Outcomes of Childhood Asthma

A high proportion of asthma presents with symptoms in early childhood, when recurring, intermittent wheeze is very common, affecting 30%–50% of infants and young children. A substantial number of children with early onset wheezing will have symptom remission during childhood, especially those with milder symptoms and an absence of severe attacks requiring hospital admission. Prospective longitudinal studies of asthma have been of vital importance to understanding the outcomes of asthma in childhood. These avoid the inevitable pitfalls of recall bias whereby adults with asthma are more likely to report symptoms in childhood than those whose asthma has resolved.[41] The Melbourne Children's Asthma Study is one of the longest-running studies of asthma in childhood, having recruited 7-year-old children with asthma and wheeze in 1964, with a supplemental recruitment of those with more severe disease at the age of 10 years. Outcomes from this seminal study have now been reported through 50 years of age and have shown that a number of factors in childhood; asthma severity, female sex, and coexistent hay fever were associated with asthma presence in mid-adulthood.[42] Furthermore, severe asthma and asthma in childhood, compared with wheezing bronchitis and healthy controls, were associated with lower forced expiratory volume in 1 second ($FEV_1$) and the ratio of $FEV_1$ to forced vital capacity ($FEV_1$/FVC) in adults; severe asthma was strongly associated with COPD despite a high proportion of this cohort being never smokers.[43] The lung function differences seen at age 50 years were not explained by between-group differences in the rate of $FEV_1$ decline in adulthood, suggesting that these differences were established in childhood and persisted ("tracked") to adult life. This observation is consistent with results of a large comparative study of adult cohorts,[44] which showed that low $FEV_1$ in early adulthood followed by physiological rates of decline was associated with COPD in a substantial proportion of participants, and supports accumulating evidence about the early life origins of COPD.[45] Another long-running cohort study of asthma in children from Dunedin, New Zealand, also showed evidence of low lung function in adults with persistent wheezing from childhood and had previously reported allergic sensitization, airway hyperresponsiveness, female sex, and smoking as risk factors for the persistence of symptoms in early adulthood and showed similar tracking of low lung function from recruitment at age 9 years.[46] In the UK, a follow-up at 50 years of children recruited in 1964 confirmed associations of childhood asthma with COPD in the absence of accelerated decline of $FEV_1$ during adulthood.[47] A report from the Childhood Asthma Management Program (CAMP) research group categorized children on the basis of trajectories of repeat lung function measurements and showed that children with persistent asthma with reduced lung function growth were at risk for fixed airflow obstruction and possible COPD in early adulthood.[48] This subject is discussed in more detail in Chapter 15.

# Severity and Mortality

## Hospitalization

As asthma prevalence increased in children in the early 1980s, there was a parallel increase observed in asthma hospitalization rates in the same countries, suggesting that the increased prevalence was not wholly explained by the increased recognition of milder cases. However, since the 1990s, hospital admission rates for asthma in children stabilized or decreased in many developed countries. In a US survey, the rates of one or more asthma attacks in the past 12 months in children remained stable over the period 2001–2010.[49] However, these trends were not replicated in all settings. A recent Scandinavian study analyzed hospital discharge codes over a 35-year period and concluded that the asthma admission rate for children had remained stable in the time period 1977–2012 at around 1 per year per 1000 children at risk.[50] The rate of admission for asthma in children in Spain fell from 20.5 to 18.8 per 100,000 from 2002 to 2012,[51] while during an almost contemporaneous period in neighboring France (2002–2010) the age standardized rate of admission in children increased by 2.5% per year.[52] Therefore, variations in time trends of hospital admission rates for asthma likely depend on factors other than the background prevalence of severity. Neighborhood deprivation was associated with increased odds for hospitalization even after taking account of maternal socioeconomic indicators in a Swedish study that included over 17,500 children admitted to hospital with asthma.[53] In a US study of geographical access to care in two states, severe asthma outcomes including emergency department visits and hospitalization differed in their associations with access to care according to a number of factors, including which outcome measure was used.[54]

Many factors have been identified that are associated with increased risk of hospitalization for asthma in children. A recent systematic review of ETS exposure concluded that children with asthma exposed to tobacco smoke were nearly twice as likely to be hospitalized for asthma.[55] The introduction of smoke-free legislation in Scotland in 2006, prior to which asthma admissions were rising at around 5% per year, was associated with a decline of 18.2% per year in both preschool and school-aged children and was independent of socioeconomic status.[56] Similar findings were reported from England when national legislation was adopted in 2007.[57]

Poor adherence to treatment has been identified as a risk for severe asthma outcomes and may be manifested by increased reliance on reliever medications. A US study used a controller-to-total asthma medication indicator in children and found that a ratio of less than 0.5 was associated with increased risk for subsequent hospitalization or emergency department attendance.[58] Psychological stress induced by the death of a close relative was associated with increased risk of asthma hospitalization in adolescents.[59] Acute exposures to environmental factors can trigger transient increases in hospitalizations for asthma. These include extremes of weather conditions,[60,61] seasonal factors, including allergen exposure and respiratory infections,[62] and air pollution.[32,63,64] Genetic factors may also increase the risk of severe asthma exacerbations in relation to specific exposures. A polymorphism of the β-2 receptor has been associated with an increased risk of hospitalization, emergency care, or intensification of treatment in children prescribed long-acting sympathomimetic bronchodilators,[65] and genetic variants in endotoxin signaling pathways can interact with indoor endotoxin exposure to increase the risk of hospitalization in children with asthma.[66]

## Severe Asthma

Although the majority of children with asthma have mild-to-moderate disease that can be managed effectively with appropriate controller medications, a proportion have severe and/or therapy-resistant disease. International consensus guidelines on the definition, evaluation, and management of severe asthma in children have been published[67] and its heterogeneity has been documented using cluster analysis in a US study.[68] A recent European study has used a case-control design to identify features of severe asthma in children compared with those with persistent but nonsevere disease. In a multivariate analysis, severe asthma was characterized by sensitization to food allergens (previously reported as a risk factor for life-threatening asthma), hospitalization and emergency visits for asthma, symptoms in response to physical activity, and lower lung function, although half the cases had $FEV_1$ within the normal range.[69] Interestingly, the cases could not be distinguished from controls by the home environment (apart from tobacco smoke exposure), parental education, or adherence to treatment.

## Asthma Deaths

An epidemic of reported asthma deaths was observed in some, but not all, industrialized HICs in the latter half of the 20th century, beginning in the 1960s.[70] Registered causes of death of 5- to 34-year-olds were analyzed from 1959 to 1979 and found to increase in New Zealand, Australia, England, and Wales, but not in the United States, Canada, or West Germany. As with all temporal trends, it is important to consider changes over time in disease classification, the way death certificates are completed and recorded, and a shift in diagnostic preferences. Of note, the return to preepidemic death rates was slower in New Zealand than in other countries, and New Zealand experienced a “second epidemic” in the 1970s, suggesting specific geographical factors in asthma management. This led to speculation that inhaled sympathomimetic drugs were implicated, supported by ecological evidence of higher sales of these (and other) asthma drugs in New Zealand, and some evidence that regular corticosteroids were underused. Further evidence from case control studies implicated the potent β-sympathomimetic drug, fenoterol in deaths due to asthma. A recent Cochrane review of another β-sympathomimetic drug implicated in asthma deaths, formoterol, considered 20 studies in adults and 7 studies in children and adolescents. All deaths occurred in adults, and the authors concluded, on the basis of low-quality evidence, that there was weak evidence of increased adverse events associated with regular use of formoterol in children[71] However, two recent multicenter RCTs comparing combination corticosteroids/long-acting bronchodilators in adults and adolescents (>12 years) using budesonide/formoterol[72] and in children (4–11 years) using fluticasone/salmeterol[73] showed noninferiority of combination treatment compared with inhaled corticosteroid alone in relation to serious asthma-related adverse events. Deaths from asthma in childhood are relatively uncommon in HICs, having declined since the 1990s. National surveillance surveys have been used to attempt to identify factors associated with increased risk of asthma mortality. In New South Wales, Australia, 20 children died from asthma over the 10-year period, 2004–2013 (http://www.ombo.nsw.gov.au/news-and-publications/publications/annual-reports/nsw-child-death-review/nsw-child-death-review-team-annual-report-2013). Risk factors for death included older age, low socioeconomic status, psychosocial problems, and Asian or Pacific Island racial background. A high proportion of those who died had a record of hospitalization in the previous 12 months; other factors identified were lack of follow-up care after admission, poor adherence to medication, and suboptimal asthma control.[74] The Royal College of Physicians in the UK led a national confidential enquiry into all asthma deaths occurring in the year commencing February 2012 (https://www.rcplondon.ac.uk/projects/national-review-asthma-deaths). Of 195 people that died, the majority had asthma diagnosed as adults and only 28 deaths were in people younger than 19 years.[75] Of all those who died, important factors identified were previous hospital admissions, attendance at an emergency department in the 12 months prior to death, failure to seek medical assistance during the final attack, and lack of specialist follow-up care. A low proportion of patients had personal asthma action plans or had received an asthma review in primary care in the year before death. Avoidable factors were identified in almost two-thirds of asthma deaths, including smoking and exposure to tobacco smoke, poor adherence to medications, psychosocial problems, and nonattendance at review appointments. In children and young people, poor recognition of the risk of adverse outcome was found to be of particular relevance.

## Quality of Life and Economic Impact of Asthma

There is little doubt that asthma impacts on the QoL of both children and their caregivers. Several factors may impact on the QoL of a child with asthma, including asthma control and health care visits, asthma attacks, medication routines, family factors, socioeconomic status, and caregiver QoL. A systematic review of the magnitude of QoL impairments in 7- to 18-year-old children with asthma compared with healthy controls found lower overall QoL and lower scores in the domains of physical, psychological, and social functioning.[76] An attempt to quantify the impact of a range of 20 chronic childhood conditions using standard health economic methods reported that asthma and allergies were the most prevalent, but had the least impact in terms of loss of quality adjusted life years (QALYs).[77] A range of asthma QoL instruments, which may be self-reported or, for younger children, parent or caregiver reported, has been developed and validated.[78] An example of a commonly used suite of questionnaires can be accessed at: https://www.qoltech.co.uk/index.htm. QoL in children with asthma is linked to poor symptom control[79] and reduced lung function.[80] However, children with equivalent measures of asthma control can have marked differences in QoL scores measured using standardized instruments, which relate, in part, to psychological and family factors, including anxiety and depression.[81,82] Recent evidence has shown that the age of a child moderates the association between asthma severity and QoL, with older children reporting a greater impact on QoL as asthma severity increased.[83] QoL impacts in childhood asthma extend to caregivers and families; in the former case, there is an interrelationship between parent/caregiver QoL and that of the child, including measures of asthma control.[84] Parents of children with poorly controlled asthma report impaired QoL for emotional and family activities.[85] There is evidence for racial disparities in the impacts on QoL of parents of children with asthma, with black and Hispanic caregivers perceiving a greater burden of their children's asthma. However, this may depend on the extent of cultural and psychological adaptation (acculturation) of these families, with less acculturation being associated with an apparent protective role in reducing the burden of asthma on urban, African-American families.[86]

In the US, the Centers for Disease Control and Prevention (CDC) has estimated the proportion of schooldays missed by children aged 5–17 years due to asthma to be equivalent to 13.8 million schooldays with slightly higher rates reported in black and Hispanic children, and in those from poorer social strata (http://www.cdc.gov/asthma/asthmadata.htm). In addition, lost productivity due to parental absence from work to care for their children with asthma accounts for a substantial proportion of the indirect costs of asthma.

As well as impacts on individuals' and families' QoL, asthma carries an economic cost to society, which can be accounted through direct health care resource costs, including emergency care, hospitalizations, physician visits and medication costs, and indirect costs incurred through loss of productivity. Many of the attempts to quantify the economic burden of asthma have been carried out in rich countries and various country-specific estimates have been published (see http://www.globalasthmareport.org/burden/economic.php). In Europe, for example, the total costs attributed to asthma in adults and children amounted to almost €34 billion ($38 billion; £26 billion) at 2011 values (ERJ White Book: http://www.erswhitebook.org/)[87] of which almost 60% was accounted for by the direct costs of health care including medications. The equivalent costs in the US are estimated to be $56 billion (€50 billion; £39 billion), of which the greatest portion is attributed to direct health care costs (https://www.epa.gov/asthma/2016-asthma-fact-sheet). Although severe phenotypes of asthma account for a small proportion of the total disease burden, they make a disproportionately high contribution to the economic costs of asthma (GINA report Global Strategy for Asthma Management and Prevention, 2015 update at: www.ginasma.it). The mean monthly costs of children with very poorly controlled asthma compared with not-well-controlled, or well-controlled disease, have been estimated to be more than twice as high.[88]

# Phenotypic Variation

## Temporal Progression of Symptoms

In a seminal paper from the Tucson Children's Respiratory Study based on wheezing history from birth to 6 years, three discrete phenotypes were described with varying associations with lung function, allergic sensitization, and outcome.[89] This study was instrumental in establishing the concept of transient early wheezing in the first few years after birth as a condition distinct from asthma and most likely to arise as a consequence of an airway developmental disorder with low airway function measured soon after birth, a lack of association with allergic sensitization, and loss of symptoms by 6 years of age. Subsequently, in recognition of the phenotypic heterogeneity of asthma and wheezing illnesses in children, several groups have taken various approaches to classifying wheezing from early childhood by temporal progression of symptoms. Most have used statistical approaches that involve clustering symptom patterns using either a single cardinal symptom (wheeze) or several symptoms combined. These methods are generally regarded as data driven with no prior stipulations about the number or characteristics of the phenotypes derived. In a large, population-based study in the UK, latent class analysis was used to derive five different temporal patterns of wheezing from birth to 7 years.[90] The important point to note here is that latent classes are not observable, so individual subjects cannot be assigned to a specific phenotype, but instead have a set of probabilities of belonging to one or several classes. Latent structures in the data are simply a way of describing variations that may have distinct underlying biological pathways (endotypes) with discoverable and preventable risk factors. Therefore, these methods are not directly translatable to the clinic but can be regarded as hypothesis-generating approaches. Replication studies in several different cohorts using latent class analysis or variants of this method confirmed the general description of these temporal classes or phenotypes.[91–94] Wheezing phenotypes that started early (within 6–18 months after birth) and persisted through mid-childhood were particularly associated with a family history of asthma, evidence of allergic sensitization, and reduced airway function in later childhood.[95] Similar associations with lung function outcomes have been reported in a Scandinavian cohort using simple categorization to different wheezing patterns; early persistent wheeze was associated with low $FEV_1$ at age 16 years and with evidence of small airway dysfunction.[96] Although all wheezing phenotypes compared with children who never wheezed show some decrement in measures of airway function in later childhood, persistent wheeze has also been associated with low growth of $FEV_1$ through adolescence.[97] Extended latent class analysis of wheeze to age 16 years has recently been reported in a UK birth cohort with similar outcomes associated with persistent wheezing phenotypes; increased bronchodilator responsiveness, lower $FEV_1$/FVC, and higher FeNO levels (Fig. 42.4).[98] Using a similar statistical approach, but including multiple data dimensions in the Leicester cohorts in the UK enabled identification of three wheezing phenotypes and two of chronic cough. These have subsequently been replicated in an independent, population-based cohort with two distinct phenotypes showing consistency between the discovery and replication samples; atopic persistent wheeze and transient viral wheeze.[99] The overall synopsis of this series of studies is that wheeze that begins in early childhood and becomes persistent is associated with a poorer prognosis than other wheezing patterns. However, the original premise to identify factors influencing different phenotypes has not materialized; known associations of transient early wheezing and low airway function in early childhood with exposure to tobacco smoke during pregnancy and factors associated with a lower incidence of lower respiratory infections in early childhood have emerged from association studies with derived phenotypes, but there were few exposures that showed clear differentiation between different patterns of wheeze.[100,101] The derived phenotypes have been shown to have external validity in a German comparison of latent class-derived and clinical phenotypes and comparison between these two enabled the discovery of a previously unrecognized clinical phenotype of intrauterine tobacco smoke exposure, decreased lung function, increased genetic risk for asthma, but without an established asthma diagnosis or treatment associated with unremitting wheeze.[94] A joint modeling approach has also been applied to data in a cohort from Manchester, where the availability of links to clinical records allowed latent class analysis of parent reported and physician-confirmed wheezing. This enabled the separation of children with persistent wheezing into those with mild, controlled disease and those with "persistent troublesome wheeze" with the latter displaying reduced lung function, increased airway responsiveness, and a marked increase in exacerbations and hospitalizations compared to the other classes.[102]

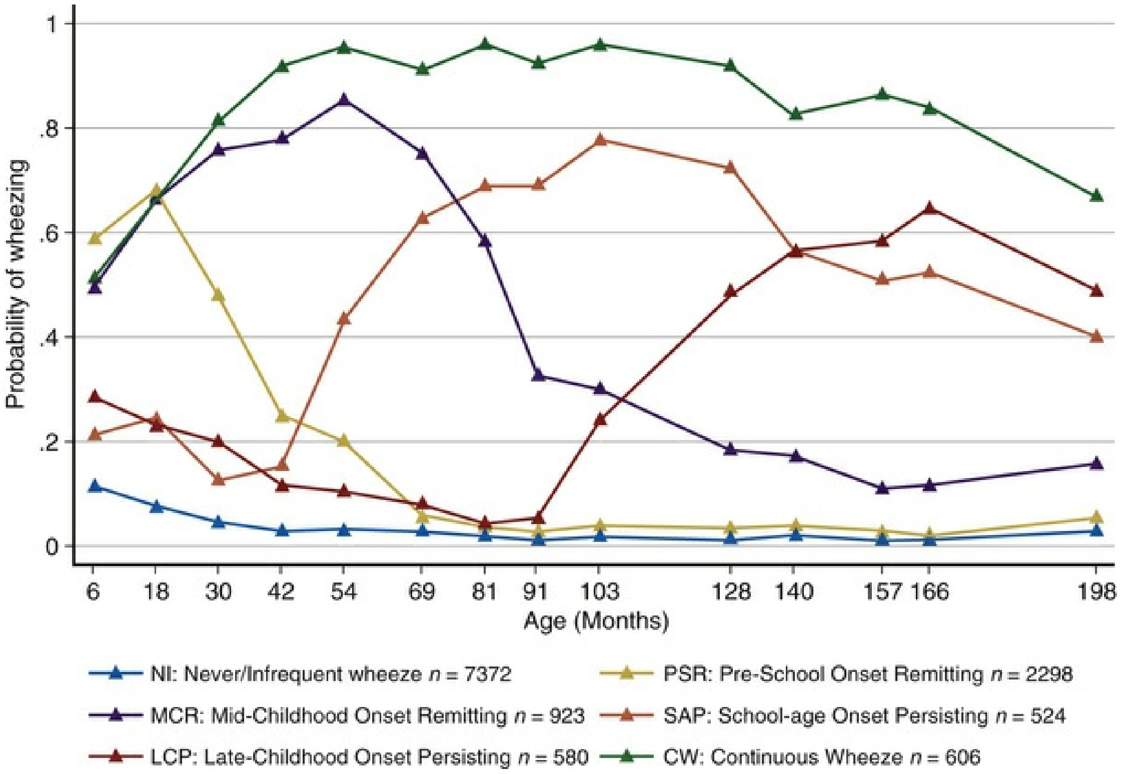

**FIG. 42.4** Estimated prevalence of wheezing at each time point from birth to 16½ years for each of the six wheezing phenotypes identified by using latent class analysis in 12,303 children. (From Granell R, Henderson AJ, Sterne JA. Associations of wheezing phenotypes with late asthma outcomes in the Avon Longitudinal Study of Parents and Children: a population-based birth cohort. *J Allergy Clin Immunol*. 2016;138(4):1060-1070.e11.)

Translating evidence from preschool wheeze in epidemiologic studies to a clinically useful phenotypic definition led the European Respiratory Society Task Force to propose discrimination between episodic viral wheeze (EVW) and multitrigger wheeze (MTW), the latter being more likely to be associated with the development of asthma, and should be treated with inhaled corticosteroids.[103] However, these phenotypes are not stable over time[104] and a bronchoscopic study including children with EVW and MTW compared with nonwheezing controls showed no differences in age of onset, symptom duration, prevalence of atopy, or markers of airway inflammation (eosinophils, epithelial loss, and basement membrane thickness) between the two wheezing phenotypes, suggesting they were part of the same spectrum of disease rather than distinct pathological subtypes of asthma.[105] In contrast, invasive studies have shown differences in bronchoalveolar lavage and endobronchial biopsy cellularity between EVW, predominantly neutrophilic, and MTW, classically eosinophilic, and there is evidence that EVW has less severe airway obstruction and impairment of gas mixing and lower FeNO compared with MTW.[106] In practice, these features may be difficult to establish clinically, and a review of the previous Task Force guidance acknowledges greater uncertainty in the distinction between early life wheezing phenotypes and their responses to pharmacological treatment,[107] although the presence of eosinophilia is likely to be associated with a beneficial response to inhaled corticosteroids.

## Inflammatory Subtypes

The classification of asthma in adults has evolved around observed biomarkers of disease, including histopathological examination of airway mucosal inflammatory subtypes. Similar approaches in children have largely been limited to specific groups that have either been sampled opportunistically during anesthesia for unrelated conditions, or have presented with diagnostic challenges or severe disease that mandated bronchoscopic investigation. Thus, such approaches have mainly been applied to the classification of more severe disease phenotypes. Less invasive markers of airway inflammation are available, including the measurement of FeNO, the assessment of inflammatory cells in induced sputum, and the measurement of inflammatory markers in exhaled breath condensate. These biomarkers have largely been evaluated in the context of asthma control or responses to specific interventions, although application to different phenotypes of asthma in children has yielded some interesting findings. Sputum examination in a subset of the UK Isle of Wight cohort showed eosinophilia in adolescent-onset disease, which was not seen in persistent asthma from the age of 10 years,[108] although the significance of this was not clear. As expected, sputum eosinophilia was greater in atopic compared with nonatopic asthma in this population. However, one of the potential pitfalls of using sputum cell counts to categorize asthma is that they may not be stable over time.[109] Raised FeNO has been associated with longitudinal wheezing phenotypes, but only those associated with allergic sensitization[110]; therefore, it has little utility in adding to the understanding of the nature of these phenotypes. Examination of peripheral blood mononuclear cells has revealed differences in immune regulatory mechanisms between nonallergic and allergic asthma,[111] and cytokine expression patterns in response to house dust mite extracts have displayed distinct immunophenotypes associated with house dust mite sensitization and asthma.[112] The development of biomarkers that can be acquired through less invasive means and their implementation through systems biology is likely to lead to a better understanding of disease processes underpinning the phenotypic heterogeneity of asthma in children and may allow the development of personalized treatments or prevention strategies.[113]

## Severe Asthma

Children with severe asthma share some distinct features, including more allergic sensitization and poorer lung function than those with mild-to-moderate disease. They contribute a disproportionate burden to health care resources and are at greater risk of severe exacerbations and death from asthma.[114] As with other forms of asthma, there is recognized phenotypic heterogeneity in this group as well. Cluster analysis of children in the US Severe Asthma Research Program (SARP) identified four different phenotypes that were characterized largely by differences in age of onset and lung function,[68] which have been combined with adult clusters from the same study to form a composite theoretical model of severe asthma phenotypes.[115] However, even within the adult clusters based on clinical variables, there was evidence of substantial heterogeneity in sputum inflammatory cell populations. Clusters identified in the SARP were replicated in an independent cohort,[116] and a separate cluster analysis of children with persistent asthma enrolled in the CAMP identified five clusters that were differentiated on the basis of the atopy, airway obstruction, and exacerbation history.[117] There was also evidence of differential responses to inhaled corticosteroids between clusters. Five clusters of severe asthma were also identified in 6- to 11-year-old children participating in the Epidemiology and Natural History of Asthma: Outcomes and Treatment Regimens (TENOR) study, in this case characterized by atopy, sex, ethnicity, and exposure to tobacco smoke.[118] Similar approaches to disaggregating different phenotypes of severe asthma have been applied to European populations. In a French study, two severe and one milder phenotype of asthma were identified by cluster analysis in 6- to 12-year-old children.[119] The two severe clusters included children who were highly atopic with mild lung function deficits and with poor control despite high-dose inhaled corticosteroids in one cluster, and slightly older children with severe airway obstruction in the other. Although no airway inflammatory markers were included, the former group had high peripheral eosinophil counts while the latter featured a more neutrophilic pattern. The predominant inflammatory cell type identified in the airways of children with severe asthma is the eosinophil, which has been identified in the airways of children with severe wheeze in the preschool age group.[120] In contrast with adults, neutrophilic inflammation does not appear to predominate in severe asthma in children.[121] There appears to be some consistency between phenotypes emerging from unsupervised cluster analyses focused on children with severe asthma and those derived from latent structures in population-based data in that the persistence of symptoms with severe exacerbations accompanied by evidence of often multiple allergic sensitization and decrements of airway function marks those children that constitute the highest burden of asthma in the pediatric population. Greater understanding of the endotypes associated with this phenotype is expected to lead to advances in the management of this often difficult to treat group.

## Atopic and Nonatopic Asthma

The most common clinically applied method to phenotyping asthma is to classify it as atopic or nonatopic on the basis of evidence of allergic sensitization. Atopic asthma is characterized by eosinophilic airway inflammation, and is associated with other allergic disorders, such as eczema and hay fever,[122] and tends to be more severe than nonatopic asthma.[123] Estimates vary about the proportion of asthma in children that is associated with atopy; up to half of asthma cases in population-based studies are classified as nonatopic. There is a difference in the relative prevalence of atopic and nonatopic asthma between countries. The population-fraction of asthma attributable to atopy has been reported to be about twice as high in affluent compared with nonaffluent countries, and in Latin America, only a small proportion of asthma is associated with atopy.[124] In children living in a poor area of Ecuador, the population-attributable fraction of recent asthma symptoms was only 2.4%, with heavy parasitic infestation strongly inversely associated with atopic wheezing.[125] Therefore, asthma prevalence in countries with high microbial and parasitic exposure may be explained by different factors than those identified in affluent countries, where atopic asthma is more likely to predominate. It has been speculated that microbial load could be a risk factor for nonatopic asthma. There is certainly evidence that microbial exposure, even in affluent settings, can be differentially associated with asthma severity in children with atopic and nonatopic asthma.[126] However, whether this mechanism is a critical pathway for asthma inception in less affluent countries remains to be conclusively determined. Associations with other putative risk factors for asthma have also been shown to have differential effects depending on the atopic phenotype. These are considered under the various categories of exposures below. It might be supposed, given the differences in exposures associated with increased risk of either atopic or nonatopic asthma, that these phenotypes would associate with clear differences in airway inflammation.

A cross-sectional study of sputum inflammatory cells and chemokines from children with atopic or nonatopic asthma based on the presence or absence of a positive skin prick test or specific serum IgE response showed that those with atopic asthma had a higher proportion of eosinophils than nonatopic asthma or nonasthma controls; however, there were no differences in sputum neutrophil percentages between the three groups, although the children with nonatopic asthma had higher total neutrophil numbers. Sputum cytokine concentrations were consistent with these findings, with atopic asthma (rather than nonatopic asthma) being associated with higher levels of interferon-gamma (IFN-$\gamma$), interleukin (IL)-2, IL-4, and IL-5, and both asthma groups having higher concentrations than the controls.[127] Although this study seems to confirm eosinophilic airway inflammation as the typical inflammatory phenotype of atopic asthma, others have reported neutrophilic inflammation in induced sputum to predominate in nonatopic asthma.[128] However, in a bronchoscopic study, no differences were reported in eosinophils and eosinophil cationic protein levels between children with atopic or nonatopic asthma, and there were no differences in neutrophils or related Th1 mediators IL-8 and tumor necrosis factor (TNF)-$\alpha$ between the asthma and the control groups.[129] Therefore, there remains uncertainty about the inflammatory endotype underpinning asthma phenotypes in children differentiated by the presence of evidence for allergic sensitization. Additionally, concepts of allergy are changing with recognition that different patterns of sensitization are associated with different manifestations of asthma (see section “Allergy, Asthma, and the Allergic March,” p. 663 for more details).

# The Genetics of Asthma

## Genetics

Changes in the prevalence of asthma over time in the latter part of the 20th century in many affluent countries have been ascribed to likely changes in environment and lifestyle; these were thought to be too rapid to be due to genetic shifts in the population, although asthma is a highly heritable disease. Twin studies were the classic design to apportion disease inception to nature (genetics) or nurture (environment and lifestyle). Monozygotic twins share the same DNA, whereas dizygotic twins will share approximately 50% of their genes on average. In the majority of cases, their early life environment will also be shared, so comparing disease outcomes between the two biological categories of twins it is possible to estimate what proportion of disease is heritable. Using this approach, a large number of twin studies have been carried out to estimate the contribution of heritable factors to asthma, and heritability estimates have generally been high, ranging from 50% to 90%. A study of over 20,000 Danish twin pairs recently not only confirmed the importance of heritable factors for asthma in childhood, but also that the importance of this diminished through the life course into late adulthood. They also reported that different genes influenced the liability to asthma in males and females, although the proportion of asthma explained by genetic factors did not differ between the sexes.[130] A Swedish study of over 25,000 twin pairs recently reported a heritability estimate for childhood asthma of 82%.[131] Therefore, it is clear that genetic factors are important in the development of childhood asthma. This does not negate the importance of environment in explaining temporal trends in asthma prevalence but it does highlight the roles of gene–environment interactions in asthma, and the influence of environment on gene expression through epigenetic mechanisms.

Methods used for the discovery of asthma genes have evolved over time,[132] driven—to a large extent—by advances in genotyping technology that have scaled up throughput and reduced costs to make it feasible to apply these technologies to population studies. The earliest studies used a candidate gene approach, which is usually applied to a case-control study, to look for enrichment of a marker for a gene of interest in cases compared with controls, either without disease or from a general population sample. In this approach, the function of the gene is known *a priori* and, unsurprisingly, genes in immune pathways have featured large in candidate gene studies of asthma. Although this is a way to test hypotheses about association of genes with asthma, it does not have any utility for gene discovery. Many candidate gene studies for asthma have been published and extensively reviewed with particular focus on those that have been replicated in more than a handful of studies.[133] Next came genome-wide approaches, initially through family linkage studies looking for cosegregation of genes with disease in family members, and positional cloning followed by GWAS in which the idea is to tag all common variations in the human genome and perform a hypothesis-free analysis of association of these SNP tags with disease. This has been made possible by high throughput genotyping platforms that type over 1 million SNPs. Through the HapMap project (the database has been retired by The National Center for Biotechnology Information) and the 1000 Genomes study (http://www.1000genomes.org/), it is possible to impute SNPs that were not directly typed. Due to of the number of tests being carried out, the false discovery burden of GWAS means that very large sample sizes are needed to have statistical power to detect "significant" associations. One of the limitations of GWAS is that it will detect only common risk variants and most results from GWAS studies in asthma to date have yielded risk alleles that together account for a small proportion of the genetic risk, leading to the so-called "hidden heredity" of asthma. Resequencing studies are now being done to investigate rare variants in asthma susceptibility.[134] Rare variants with large effects have been postulated to contribute to the hidden heritability of asthma, although recent evidence suggests that this may not be as important as previously thought.[135] A meta-analysis of 20 genome-wide linkage studies identified two regions (2p21-p14 and 6p21) with evidence of linkage to asthma in European families.[136] Large GWAS of asthma in children and adults have identified SNPs associated with asthma at genome-wide levels of significance, which have been replicated in independent populations.[137,138] The association of asthma with SNPs in the 17q21 region was shown to be primarily with asthma of childhood origin.[139,140] This has been confirmed in a recent GWAS of age of asthma onset with additional regions (9p24 and 17q12-q21) which was also associated with the earlier onset of asthma.[141] Other asthma phenotypes have been considered, and GWAS have discovered associations with the asthma, hay fever/rhinitis phenotype,[142,143] and childhood asthma with severe exacerbations.[144] In the latter case, the susceptibility locus *CDHR3* was subsequently found to mediate binding and replication of human rhinovirus (HRV) C.[145]

## Gene–Environment Interactions

Knowledge that environmental factors and the timing of exposure are important associations of asthma onset in early childhood has focused attention on interactions between genetic and environmental influences explaining variations in asthma risk. One consequence of assembling the very large consortia needed for GWAS studies is that they tend to come from widely varying geographical distributions and hence a very heterogeneous exposure background, which could reduce the chances of detecting genetic associations in GWAS. Most gene–environment interaction studies to date have taken a candidate gene approach, seeking to find evidence that genetic variation in known biologic pathways or with known associations with asthma modifies the effect of an exposure on asthma outcomes. These have included interactions with infectious agents, notably genetic variants in the *CD14* gene and endotoxin exposure,[146] and interaction between HRV infection and *17q21* genetic variants, a risk locus discovered in a GWAS of asthma.[147] Following the discovery that 17q21 SNPs were associated specifically with childhood onset asthma, an interaction between variants at this locus and tobacco smoke exposure was reported.[139] A number of other candidate gene studies of genetic interactions with tobacco smoke exposure on the risk of asthma or asthma exacerbations have been published.[148] These have shown interactions of various genetic regions with prenatal and/or postnatal tobacco smoke exposure and asthma risk. Gene–environment interaction can also be used in a nontargeted way to identify new genetic associations with asthma. A genome-wide interaction study (GEWIS) of interactions with tobacco smoke exposure in a European consortium of birth cohorts found evidence for interaction between *in utero* and early childhood exposure with novel genetic variants.[149] Interestingly, this approach did not identify interactions with variants in genes previously reported to interact with tobacco smoke exposure in the etiology of asthma, including *TNF*,[150] *GSTP1*,[151] and *ADAM33*.[152] Another GEWIS of children from farming communities in Europe, where endotoxin exposure has been associated with protective effects on asthma and allergy, found no strong evidence for new or previously reported polymorphisms interacting with farm exposure on asthma risk. This included SNPs that had previously been reported in association with asthma or had shown interaction with farming exposure.[153] As with GWAS, which are essentially hypothesis free, there is a high statistical penalty for multiple testing; therefore, large studies are required to have sufficient power to detect interactions, especially for polymorphisms that have a low minor allele frequency.

Other exposures for which evidence of gene–environment interactions related to asthma risk have been found in candidate gene studies include the outdoor environment with genes in antioxidant and inflammatory pathways pollutants.[154–156] In the indoor environment, interactions between gas cooking and glutathione-S-transferase M1 *(GSTM1)* null mutations were described in relation to bronchial responsiveness in adults.[157] A study of indoor mold exposure found no evidence of interactions with *GSTP1* mutations in childhood asthma.[158] (See Table 42.1 for details of candidate genes implicated in gene–environment interactions.)

## Table 42.1

### Genes and Gene Regions Cited in Gene–Environment Interaction Studies of Childhood Asthma

| **Gene or Region** | | **Gene Name** | **Location** | **Function** |
|---|---|---|---|---|
| *CD14* | | Cluster of differentiation 14 | Chr5 | Encodes a surface antigen that is preferentially expressed on monocytes/macrophages and acts a coreceptor for bacterial lipopolysaccharide |
| 17q21 | *ORMDL3* | ORM1-like protein 3 | Chr17 | The *ORM* genes are a conserved gene family that act as negative regulators of sphingolipid synthesis |
| | *GSDMB* | Gasdermin B | | Encodes a member of the gasdermin-domain containing protein family, which are implicated in the regulation of apoptosis in epithelial cells, |
| *TNF* | | Tumor necrosis factor | Chr6 | Encodes a multifunctional proinflammatory cytokine that belongs to the *TNF* superfamily |
| ADAM33 | | A disintegrin and | Chr20 | Encodes a member of the *ADAM* family of |

| | | | |
|---|---|---|---|
| | metalloproteinase domain 33 | | membrane bound proteins involved in cell–cell and cell–matrix interactions. |
| **GLUTATHIONE-S-TRANSFERASES** | | | |
| *GSTM1* | Glutathione-S-transferase Mu 1 | Chr1 | *GSTs* are a family of enzymes that play an important role in detoxification by catalyzing the conjugation of many hydrophobic and electrophilic compounds with reduced glutathione |
| *GSTP1* | Glutathione-S-transferase Pi 1 | Chr11 | |
| *GSTT1* | Glutathione-S-transferase Theta 1 | Chr22 | |

## Epigenetics

Epigenetics refers to changes in the way genes are expressed as opposed to changes in their structural sequence. This provides a mechanism by which the ability of cells to read a genetic code can be open or silenced, effectively controlling whether genes are active or dormant in a cell. A number of modifications determine gene expression, including DNA methylation, chromatin remodeling, histone modification, and the action of noncoding RNAs. Of these, the most studied to date is DNA methylation, which is technically the most straightforward to assay using current technology. Therefore, epigenetic modification is a phenotype, which can indicate responses to environmental exposures or stressors, providing a link between exposure and gene expression, and which can be transmitted to daughter cells making such modifications potentially heritable across generations (transgenerational epigenetic inheritance). Studies of DNA methylation of relevance to asthma include those which have studied epigenomic changes in association with pertinent exposures, such as tobacco smoke exposure and air pollutants, and intergenerational studies linking ancestral exposures to disease in subsequent generations. Tobacco smoke exposure during pregnancy has been associated with global DNA methylation and gene-specific effects in neonatal or cord blood,[159–161] which can persist into childhood.[162–164] Air pollution exposure has been associated with effects on DNA methylation in infants' cord blood, which was dependent on the type of pollutant and timing of exposure during pregnancy.[165] In inner-city children with asthma, DNA methylation of specific gene loci in peripheral blood differed from control children from the same environment.[166] Mammalian cell DNA methylation is reprogrammed on a global scale at two points in the life cycle: at fertilization of the zygote and in primordial germ cells[167]; however, there is still uncertainty about the heritability of epigenetic marks between generations. There have been studies of the relationships of grandparental exposures with outcomes in second-generation offspring. Grandmothers' smoking during pregnancy has been associated with asthma in her grandchild, even when the mother did not smoke during pregnancy.[168] In a UK cohort, this association was limited to paternal grandmothers' smoking, and was stronger for female than for male descendants.[169] The DNA methylation in the grandchildren was not measured in either of these observational studies, but in the Norwegian Mother and Child Cohort, grandmothers' smoking when pregnant with the mother was not associated with altered grandchild cord-blood DNA methylation at loci, which was previously reported to be associated with maternal tobacco smoking during pregnancy.[170] The availability of high throughput arrays will shortly enable epigenome-wide association studies (EWAS) to be carried out in large case control studies of children with asthma using a similar hypothesis-free approach to GWAS.

# Environmental Influences on Asthma

## Pregnancy and Childbirth

### Maternal Factors

The heritability of asthma has long been recognized, but there has also been a parent-of-origin effect described with a stronger association of maternal than paternal asthma with offspring asthma.[171] This could be explained by genetic imprinting, maternal exposures during pregnancy, immune interactions between the mother and fetus, or a shared postnatal environment. In the prospective, population-based UK Isle of Wight cohort, a sex-dependent parent-of-origin effect was reported; maternal allergy was associated with asthma only in girls, and paternal allergy was associated with asthma only in boys.[172] This led the authors to speculate that epigenetic programing might be important in determining the differential effect of parental allergic disease on the risk of asthma in their offspring.

There has been increasing recognition of the role of early life factors in the etiology of asthma, extending to the intrauterine environment. This reach has extended yet further to influences prior to conception, particularly with the recognition of the potential for epigenetic marks to be both heritable and responsive to environmental challenge.[173] Maternal obesity before pregnancy was reported to be associated with an increased risk for offspring asthma independent of gestational weight gain in the Danish national birth cohort,[174] and similar observations were seen in the Generation R study for preschool wheeze.[175] The mechanisms of these observations have still to be explained, but there are suggestions that they may operate through nonallergic pathways as the excess risk appears to be associated with nonatopic asthma. Part of the association, but not all, can be explained by the association between maternal and offspring BMI and the relationship between the latter and asthma.[176] Younger maternal age also has been associated with increased asthma risk in their offspring in populations of white, European descent although the obverse of this relationship was recently reported in US Latino populations.[177] Although evolving interest in preconceptual influences and transgenerational effects is likely to continue, there is considerable literature on maternal exposures during pregnancy and the risk of subsequent asthma in their offspring.

The health of a mother during pregnancy can have important effects on the health and development of her fetus. Some maternal diseases and complications of pregnancy have been associated with an increased risk of asthma in the offspring. These include hypertension and preeclampsia,[178] anemia,[179] and the use of a number of drugs used to treat mothers during pregnancy. Antibiotic prescription during pregnancy has been associated with an increased risk of offspring asthma, although this may be confounded by shared familial factors.[180] Acetaminophen use by women during pregnancy also has been associated with an increased risk of asthma and wheezing in their offspring. A meta-analysis of published observational studies found a positive association between asthma and any use of acetaminophen in the first trimester, but noted a high degree of heterogeneity between studies, and an attenuation of the association when adjusting for respiratory tract infections.[181] Recent analysis of a large Scandinavian cohort study with detailed information on the indication for use of acetaminophen, reported associations between prenatal use and asthma in children, which could not be completely explained by confounding by indication.[182] Additionally, this study was able to consider maternal use outside pregnancy and paternal use of acetaminophen, neither of which was associated with offspring asthma, suggesting unmeasured confounding was having little influence on these associations. To date, these observational studies have not been confirmed by experiment and there has been sufficient uncertainty to deter any change in guidelines for the use of acetaminophen during pregnancy.

## Maternal Lifestyle and Environment

Exposure to maternal smoking during pregnancy is associated with increased asthma risk in the offspring. A systematic review of 43 studies concluded that prenatal tobacco smoke exposure was associated with an increased risk of asthma and wheeze, particularly in younger children, but could not separate out the effect of postnatal exposure due to the limited number of studies of children only exposed after birth.[183] Another systematic review found evidence that not only active smoking but also passive exposure of pregnant women to tobacco smoke was associated with an increased risk of asthma and wheezing in their offspring.[184] A collaborative study based on 15 European birth cohorts comprising nearly 28,000 children has found evidence that both active smoking and passive exposure of pregnant women, and the exposure of infants to maternal smoking postnatally, were associated with an increased risk of offspring wheeze in early life. The highest risk was associated with combined active maternal and passive exposure in the prenatal period.[185] Pregnant women's exposure to air pollution has also been shown to be associated with asthma in their offspring in a Chinese study of traffic-related nitrogen dioxide ($NO_2$) exposure with evidence of trimester-specific effects.[186] Similar findings regarding fine particulate ($PM_{2.5}$) exposure in mid-gestation were reported from a US population, where high levels of exposure from weeks 16 to 25 of gestation were associated with the development of asthma.[187]

Maternal diet during pregnancy has been studied extensively after observational associations suggested a link between dietary constituents and the occurrence of wheeze and asthma in the offspring. This body of research has culminated in RCTs of interventions in pregnancy as a strategy for the primary prevention of asthma. In prospective observational studies, vitamin deficiency has been elicited as having a strong association with increased asthma risk. Several studies based on estimated dietary intake of vitamin D of women during pregnancy consistently reported increased rates of asthma and allergic diseases in the offspring, although the results of studies using measurements of vitamin D status at various points during pregnancy were less conclusive.[188–191] In the long-running Aberdeen SEATON study, low intake of both maternal vitamin D and E during pregnancy have been associated with asthma outcomes during childhood up to 10 years of age, and low maternal $\alpha$-tocopherol levels in early pregnancy were confirmed to be related to a higher risk of asthma.[192] The observational evidence that vitamin deficiency and particularly that of vitamin D, which has several bioregulatory functions that are in plausible asthma etiologic pathways, led to the development of supplementation trials in pregnant women. Although they used different dose regimens of vitamin D supplements, two RCTs have reported a lower incidence of wheezing illnesses in early childhood and physician-diagnosed asthma to the age of 3 years.[193,194] Short-term differences in sensitization to aeroallergens have also been reported following vitamin D supplementation during pregnancy.[195] The longer-term effects on confirmed asthma outcomes are awaited.[196,197] Vitamin E supplementation in pregnancy has been suggested to reduce the risk of preeclampsia, although the evidence from RCTs of this intervention do not support benefit in either maternal preeclampsia or neonatal outcomes.[198] A dietary intervention has been proposed to optimize vitamin E intake with the objective of reducing asthma in the offspring;[199] however, although a pilot study was completed (ClincalTrials.gov NCT01661530 https://clinicaltrials.gov/), the results of a definitive trial are yet to be published. A follow-up of offspring from a high-dose vitamin C and E supplementation trial for preeclampsia found no differences in respiratory outcomes of infants to the age of 2 years.[200] In addition to antioxidant vitamins, there is longstanding interest in the role of long-chain polyunsaturated fatty acids (PUFAs) in the etiology of allergic diseases, including asthma. A systematic review of dietary exposure to or supplementation with PUFAs during pregnancy found that the majority of observational studies reported a beneficial effect of increased n-3 long-chain PUFA or fish intake (a rich source of these) on lower rates of allergen sensitization or atopic eczema in infancy.[201] However, an RCT of fish oil supplementation during pregnancy that followed the offspring through 6 years did not find evidence to support a reduction of IgE-mediated sensitization in the supplemented population.[202] There is no current evidence to support n-3 PUFA supplementation in pregnancy, or during breast-feeding after birth, to reduce the occurrence of asthma or wheeze in the offspring.[203] The gradient in asthma prevalence in Europe (http://www.globalasthmareport.org/burden/burden.php) has raised the prospect that a Mediterranean diet could be protective against asthma and thus contribute to the lower prevalence seen in countries in Southern compared with Northern Europe. However, a systematic review of dietary patterns and asthma did not find strong evidence to support that a Mediterranean diet in pregnancy reduces the risk of asthma in children.[204] There is currently no trial evidence to support a Mediterranean diet in pregnancy as a primary prevention strategy for asthma in the offspring.

There is good evidence in mammalian species that prenatal stress has biological effects on the evolving neuroendocrine system,[205,206] and may lead to dysregulated immune development and allergic diseases in the offspring. A recent systematic review of published studies reported that the majority showed positive associations between prenatal maternal stress and asthma or wheezing in the offspring.[207] However, the authors pointed out several methodologic caveats, including the use of self-reported instruments for exposure and outcome assessments, and the potential information bias arising from women with higher stress levels possibly reporting more asthma symptoms in their children.

## Fetal Growth and Birth Size

Size at birth has been extensively studied in relation to subsequent history of asthma and allergies in childhood. Low birth weight (<2.5 kg) is reported to be a risk factor for wheezing[208] and asthma[209,210] in childhood. Conversely, increased neonatal size (weight, length, and head circumference) has been found to be positively associated with asthma, but not allergic sensitization in children. In a US study, low birth weight was associated with a specific asthma phenotype that manifested in mid-childhood and persisted to adolescence.[211] The sometimes conflicting evidence about birth size and asthma can, in part, be attributed to the definitions used to categorize birth size, including whether gestational age at birth was used to stratify low birth weight. Preterm delivery is associated with asthma symptoms,[212] and, in a large European collaborative meta-analysis, this largely explained the association of low birth weight with asthma.[213] In the Dutch Generation R study, antenatal growth measures were available from repeat fetal ultrasound estimates during pregnancy. In an analysis of preschool asthma symptoms, no associations were found with predefined restricted or accelerated fetal growth, although accelerated weight gain in the first 3 months after birth was associated with asthma symptoms suggesting postnatal growth may be more important than fetal growth in the development of asthma.[214] An alternative explanation is that rapid postnatal growth acts as a marker of intrauterine growth restraint, which is associated with developmental effects on lung growth, which, in turn, may manifest as early asthma symptoms. In studies that have measures of lung function shortly after birth, evidence of airway obstruction in infancy has been shown to be associated with the subsequent development of asthma and wheezing.[215–217] In the Generation R cohort, lower gain of fetal weight and length between the second and third trimester of pregnancy were associated with higher airways resistance and physician-diagnosed asthma in mid-childhood, providing a mechanism by which fetal growth restriction could influence the etiology of asthma symptoms in children.[218]

## Mode of Delivery

In concert with the rise in asthma prevalence experienced in many developed countries in the late 20th century, there was a rise in the rates of births by cesarean section, including in low-risk pregnancies (http://www.cdc.gov/nchs/fastats/delivery.htm). Knowledge that cesarean delivery was associated with differences in microbial colonization of the newborn gut led to speculation that this could influence postnatal immune development and increase the risk of asthma and allergy.[219–221] A substantial number of studies compared asthma risk in children born by cesarean section compared with children delivered vaginally, and, although not all confirmed a positive association between the mode of delivery and asthma, two meta-analyses in 2008[221a,221b] and a more recent one have reported a consistent overall increased risk of asthma in children born by cesarean section of about 20%.[222] A study from Denmark suggested that this association was more pronounced in children who were delivered by cesarean section before membrane rupture.[223] However, there remains doubt about the proposed biological mechanisms for this association. Increased asthma risk has been associated with emergency, but not elective, cesarean section delivery, suggesting that factors associated with the indications for emergency delivery may be more important than early gut colonization.[224] Association between cesarean section delivery and directly measured outcomes are not entirely consistent with the increased risk of reported asthma and wheezing. Although cesarean section delivery was associated with persistent preschool wheezing in the Dutch Generation R study, there was no association with airway resistance and only elective, but not emergency, cesarean section was associated with raised FeNO levels.[225] A follow-up to adolescence of a German study of healthy term newborns found no increased risk of asthma and no difference in lung function at age 15 years according to the mode of delivery.[226] However, recent population-based studies based on linkage data report a small increased risk of hospital admissions for asthma in children born by cesarean section compared with vaginal delivery,[227–229] suggesting that there is a true but modest association that remains to be explained biologically.

## Early Childhood

### Breast-Feeding Diet

Dietary intake could affect asthma development in many ways, through ingestion of allergens, modification of the gut microbiota, rate of growth and development of obesity, or specific nutrients acting directly on immunological and pulmonary development. Patterns of breast-feeding infants vary between HICs and low- and middle-income countries (LMICs); with both the rate of initiation of breast-feeding and the duration of exclusive breast-feeding being lower in HICs than LMICs.[230] The coincidence of low breast-feeding rates with high asthma prevalence in HICs has suggested breast-feeding as a possible protective influence on asthma and allergic diseases. Many observational studies have considered the association between asthma risk and breast-feeding in infancy. They have used different metrics of exposure, including ever-versus-never breast-feeding and the duration of any, more, or exclusive breast-feeding, studied either general or high-risk populations and comprised a combination of prospective cohort, case-control, and cross-sectional study designs of varying methodological quality. Two key considerations in evaluating these studies are confounding; breast-feeding is strongly socially patterned and is therefore prone to confounding by other lifestyle and environmental variables and bias; parents with personal or family histories of asthma or allergies may be more or less likely to adopt breast-feeding in the belief that it will prevent disease in their offspring. A systematic review identified 42 reports of asthma and wheezing at 5–18 years of age in association with breast-feeding, with the majority of these being from high-income settings. Pooled odds ratios from a meta-analysis showed evidence of a protective effect on asthma risk of any breast-feeding compared with no breast-feeding, and more breast-feeding compared with less breast-feeding, with both effects being stronger in LMICs than HICs.[231] A separate systematic review and meta-analysis using different search criteria identified 117 studies reporting asthma outcomes (asthma ever, recent asthma, and recent wheezing illness) in association with breast-feeding history. This also reported evidence to support a protective effect of breast-feeding on asthma risk for all three outcomes considered.[232] Age-stratified analyses showed that this effect was strongest in young children aged 0–2 years when asthma is difficult to differentiate from other causes of wheezing illness and diminishes with time. It is possible that the effect observed resulted from protection against early respiratory infections and associated wheezing in early life. In contract with the results of the meta-analyses cited above, a large population-based study of Hong Kong Chinese children found no association between exclusive or partial breast-feeding and hospitalization for asthma[233] In contrast with many lifestyle choices that are not conducive to randomized trials to strengthen the evidence base, there has been an innovative cluster-randomized trial of breast-feeding promotion carried out in Belarus: the PROBIT trial,[234] which successfully increased the rates of breast-feeding exclusivity and duration in the intervention arm. Despite this, there were no differences in rates of asthma or skin prick sensitization assessed by pediatricians at a follow-up clinic when the children were 6 years old.[235] Thus, it appears likely, on the basis of current evidence, that the apparent protective effects of breast-feeding on asthma could be explained by a combination of confounding and variation in phenotypic definition of the outcome, which includes infection-associated wheeze in preschool children. Breast milk could be a source of dietary allergen ingestion by the infant. Trials of allergen restriction in the diets of pregnant and lactating mothers showed little evidence of a beneficial effect on asthma in their offspring, and observational studies of high- compared with low-allergen-containing diets produced conflicting results.[236] There has been a recent shift in thinking about allergen avoidance in early life, including lactation, as a means of primary prevention of food sensitization in particular. Publication of the results of the LEAP study[237] provided robust evidence that tolerance to peanut sensitization could be induced by the consumption of peanut allergen by infants. However, a randomized trial of the introduction of allergenic foods to breast-feeding mothers did not show a reduction in food allergies in a population-based sample of infants.[238] Therefore, current evidence does not support modification of maternal diet during lactation and breast-feeding, either by allergen reduction or supplementation, but there is a lack of data on asthma outcomes from well-conducted clinical trials.

### Childhood Diet.

Interest to date in the relationship between diet and asthma in children has centered on the potential modifying effects of dietary constituents on oxidant-antioxidant balance and their role in regulating airway inflammation.[239] Much of the evidence to date comes from observational studies, many cross-sectional, of dietary intake of foods, such as fruit and vegetables, dietary patterns, including the Mediterranean diet, and specific nutrients, such as vitamins and trace elements. One of the difficulties of interpreting this evidence arises from the methods used to categorize the intake of various nutrients, usually relying on food frequency questionnaires or diet diaries. Therefore, the epidemiologic evidence needs to be viewed with caution. In the cardiovascular literature, there are examples of evidence from randomized trials going in the opposite direction of effect from associations seen in observational studies[240]; that is, the vitamin intake that was "protective" in observational studies was associated with increased cardiovascular and all-cause mortality in trials of supplementation. There are currently few randomized trials of nutritional interventions in relation to children's asthma, and the evidence from trials of supplementation with specific food items in adults have been generally disappointing.[241,242] A synthesis of systematic reviews of diet and asthma in children and adults was undertaken under the auspices of the European Academy of Allergy and Clinical Immunology. This limited its search strategy to foods and diets but not nutrient supplements in relation to asthma outcomes, and identified seven systematic reviews that met quality criteria.[243] The synthesis of evidence from these reviews concluded that there was a beneficial effect of a high intake of antioxidant vitamins C, D, and E, and fresh fruit and vegetables, and of adherence to a Mediterranean dietary pattern in reducing the risk of asthma, with most of the beneficial effects being observed in children.[244,245] A meta-analysis of vitamin D supplementation in children with asthma found some evidence to support this supplementation to reduce asthma exacerbations, but the evidence was of low quality and not consistent for other indicators of asthma control.[246] However, vitamin D supplementation for the primary prevention of asthma rather than to improve asthma control is currently limited to prenatal interventions. In contrast to the evidence that the traditional diets, including the Mediterranean diet, may be protective for asthma, there has been concern that the introduction of highly processed “fast food” into the Western diet could be implicated in the rising prevalence of childhood asthma. In the ISAAC phase 3 study, a consistent association was found between questionnaire-reported frequency of fast food intake and asthma in children and adolescents.[247] However, on the basis of the current state of knowledge, there are no dietary interventions beyond pregnancy and early infancy that can be recommended specifically to lower the risk of developing childhood asthma. The role of the Mediterranean diet comprising a high proportion of fruit, vegetables, grains, and fish with olive oil contributing the chief source of fats, remains a topic of intense interest as there is observational evidence of a beneficial association between adherence to this dietary pattern and a number of health-related outcomes, including metabolic syndrome, cardiovascular disease, and type 2 diabetes as well as asthma. There is accumulating evidence that such benefits could result from immunomodulatory effects of the diet mediated through the gut microbiome.[248] The microbiome is the combined genetic material of all microorganisms in a particular environment and access to this information has been facilitated by modern, rapid DNA sequencing technology. According to the Gut Microbiome Project, the number of genes represented in the gut microbiome probably exceeds the number of human genes by at least two orders of magnitude (http://genome.wustl.edu/projects/detail/human-gut-microbiome/). Therefore, a complex interplay exists between nutrients and their metabolites, gut microbiota, and human immune cells. Adherence to a largely plant-based Mediterranean-type diet has been associated with a more favorable gut microbiome.[249] Targeted interventions to restore the healthy human microbiome may become an effective strategy to reduce the burden of asthma and allergic disease.[250]

## Obesity

In parallel with the increased prevalence of asthma experienced in many developed countries in recent decades, there has been a large increase in childhood obesity in these countries. In the United

States, childhood obesity has more than doubled over the last 30 years,[251] but the rate of increase has been even higher in developing countries (http://www.who.int/end-childhood-obesity/facts/en/). According to the World Health Organization (WHO) there will be a global increase to 7 million overweight or obese infants and young children by 2025. However, the contemporaneous increase in the prevalence of two conditions does not necessarily infer a direct relationship between them, far less a casual one. The epidemiologic evidence does support a positive association between overweight or obesity and asthma in children, and there is some evidence from adult studies of a temporal order of association with overweight/obesity preceding incident asthma.[252] Obesity is defined in adults as a BMI ≥ 30 $kg/m^2$ and overweight as a BMI ≥ 25 $kg/m^2$; age-specific values have been derived by the International Obesity Task Force, but different definitions have been used in the literature. A recent systematic review synthesized the evidence for the relationship between overweight and obesity with asthma in 38 studies that included over 1.4 million children. There was a positive relationship between increased BMI and asthma with some evidence of a "dose-response" with obesity having a stronger association than the overweight category, although there was substantial heterogeneity between studies.[253] Both asthma and obesity are complex polygenic diseases, and a number of possible explanations have been advanced to explain their coexistence. These include a common genetic background, mechanical changes in lung function associated with high body weight, changes in physical activity and diet, increased insulin resistance, and systemic inflammation, but evidence is still lacking to support a direct causal link.[254,255] So, the question remains whether high body mass causes asthma, potentially through the inflammatory influence of adipokines,[256] or that asthma and obesity share common etiologic pathways. Other possibilities are that this is a stochastic (random) association between two highly prevalent entities or that it is spurious and due to increased respiratory symptoms experienced by the obese, which are misinterpreted as asthma. Shared genes underpinning obesity and asthma were first suggested by linkage studies pointing to the β-adrenergic receptor, TNF-$\alpha$, glucocorticoid receptor-β, and leptin genes, but none of these loci was associated with asthma in a GWAS, which indicated *DENND1B* variants to be associated with BMI in children with asthma.[257] A large number of genetic variants have now been identified from GWAS of obesity. A genetic risk score for BMI in children based on 32 of these SNPs was used in a Mendelian randomization study of BMI and asthma in children. This showed that higher BMI predicted from the genetic risk, and this, unconfounded by lifestyle and environment, was associated with an increased risk of asthma, lending some support to the existence of a true causal relationship.[258] This is further supported by intervention studies of weight-loss programs in obese patients with asthma, which have reported improvements in asthma control, bronchial responsiveness, and markers of airway inflammation.[259] A small RCT of diet-induced weight loss in obese children with asthma has confirmed some of these findings with reported improvement in asthma control, but without any observed changes in markers of airway or systemic inflammation.[260] Another trial of a multifactorial intervention that achieved weight loss in obese children with asthma also reported improvements in asthma control and lung function measures, although airway inflammation was not assessed.[261] These results mirror those in adult studies, which suggest that the mechanism of improvement in asthma control associated with weight loss are mediated through factors other than reduction in airway inflammation.[262]

## Infections

Viral wheezing illness in early life is common, and affects around one-third of infants and young children. Viruses are also well recognized as the most frequent triggers of asthma in both adults and children. The two virus species that have received the most interest in relation to asthma development in early life are respiratory syncytial virus (RSV) and HRV. The growing interest in HRV infection is associated with modern molecular techniques of viral identification as it grows poorly in standard viral culture. RSV is a common cause of hospitalization for bronchiolitis during infancy and has long been recognized to be associated with postbronchiolitic wheezing. Serological evidence suggests that the vast majority of young children have encountered RSV infection by

2–3 years of age. So the question has been whether continued wheezing illnesses and subsequent diagnosis of asthma after bronchiolitis in infancy indicates a causal role for RSV in asthma development, or that hospitalization for RSV bronchiolitis is selective of those infants with either or both airway and immunological developmental features that already predispose them to later wheezing and asthma. A series of follow-up studies of a Swedish case control study of infants who were hospitalized with severe RSV bronchiolitis in their first year has shown an increased risk of asthma and allergic sensitization in the bronchiolitis group compared with healthy controls. This cohort has now been followed to age 18 years and the early findings have persisted.[263] Young adults who were hospitalized for RSV in infancy compared with controls had increased prevalence of asthma and allergic sensitization, lower $FEV_1$/FVC, and increased airway responsiveness. Shorter-term cohort studies have also reported an increased risk of wheezing, asthma, and lower $FEV_1$ following hospitalization for RSV bronchiolitis in infancy.[264,265] In an observational study of a randomized trial of montelukast after bronchiolitis, a family history of asthma, aeroallergen sensitization, and the severity of RSV infection were predictors of asthma at age 6 years.[265] It is possible that differences in outcomes from previous cohort studies that followed children hospitalized for bronchiolitis in infancy, but reported no increased risk of asthma, could be explained by the inclusion of a greater proportion of milder cases in population-based samples compared with clinical samples. The familial association of asthma with severe RSV bronchiolitis has recently been explored in genetic epidemiologic studies, showing a number of shared genes associated with the severity of response to RSV infection and asthma risk.[266] This evidence provides a plausible causal link between a severe RSV lower respiratory infection in infancy and an increased asthma risk in later childhood. Empirical evidence of differences in immune responses to RSV infections and subsequent asthma has also been provided by studies of blood and airway chemokines and cytokines during infection in relation to subsequent asthma. Gene variants in *ILRL1,* an asthma-associated gene, and ILRL1-a expression in the upper airway have been reported in association with severe RSV bronchiolitis.[267] Increased expression of CCL5 (RANTES) in the upper airway at the time of severe RSV bronchiolitis, in addition to the development of aeroallergen sensitization, has been linked to an increased risk of subsequent asthma.[268] Thus, there is a shifting focus to innate and adaptive host responses and their dysregulation in the etiology of asthma,[269] and therefore the therapeutic potential of immunomodulatory interventions, such as vaccines in primary prevention.[270,271] Meanwhile, trials of therapeutic interventions with antiinflammatory medications after bronchiolitis have been generally disappointing. Treatment with long-term, high-dose inhaled corticosteroids following hospitalization for RSV bronchiolitis has not been shown to influence respiratory outcomes.[272,273] Systematic reviews of leukotriene inhibitors after bronchiolitis in young children show that they may reduce symptoms of postbronchiolitic wheezing, but there is no evidence of a beneficial effect on the longer-term outcomes of recurrent wheezing or the use of inhaled corticosteroids for asthma.[274,275] The macrolide antibiotic azithromycin has been shown to reduce neutrophilic airway inflammation in a murine model of viral bronchiolitis[276] and has been shown to reduce the risk of subsequent severe lower respiratory infections in children with a history of such infections.[277] In a proof-of-concept trial, 14 days treatment with azithromycin after bronchiolitis was shown to reduce upper airway levels, but not serum IL-8 levels, and to reduce respiratory symptoms in the succeeding 12 months after illness.[278] Immunoprophylaxis for RSV with palivizumab is currently restricted to infants at high-risk of severe RSV bronchiolitis, so results may not be generalizable to the general population. Short-term reductions in the frequency of wheezing symptoms have been reported in palivizumab-treated preterm infants[279,280] and, although suggestions of lower asthma prevalence in association with better adherence to palivizumab were reported in a retrospective analysis of an eligible cohort, this evidence needs to be confirmed in further studies[281] and in term infants at high risk for asthma.

A complex interplay between early life viral infection, host immune responses, and interactions with allergic sensitization in the genesis of asthma has also emerged from studies of the relationships between HRV infection and subsequent asthma risk.

HRV is the most common virus identified in early life wheezing illnesses.[282] The association of early HRV-associated severe respiratory illnesses and subsequent wheezing and asthma was initially reported in a Finnish observational cohort study followed to 11 years of age. Prospective birth cohort studies have since confirmed this association.[283,284] The Childhood Onset of Asthma (COAST) study in the US has been instrumental in uncovering the mechanisms underlying this strong association (http://www.medicine.wisc.edu/coast/family). A recent follow-up of this high-risk birth cohort has shown a strong positive association between HRV and not RSV with regard to wheezing in the first 3 years and asthma at age 13 years (Fig. 42.5).[285] There was also evidence that the presence and timing of aeroallergen sensitization was associated with subsequent asthma in this cohort; 65% of those sensitized in the first year compared with 40% sensitized by 5 years but not in the first year and 17% not sensitized by age 5 years, had asthma at 13 years and there was an additive effect with HRV wheezing illnesses. Furthermore, a temporal analysis of the association between allergic sensitization and viral wheezing illnesses in the COAST study has shown that allergic sensitization increases the risk of wheezing illnesses caused by HRV; however, the converse, HRV wheezing preceding allergic sensitization, was not supported.[286] This suggests a causal role for allergic sensitization in the biological pathway of asthma development following respiratory infection, particularly with HRV. Blunting of the seasonal increase of asthma exacerbations associated with viral infections by pretreatment with omalizumab provides additional support for the pivotal role of allergic sensitization in modifying the response to viral infections in the asthmatic airway.[287] The risk of subsequent asthma following HRV infection has also been found to be enhanced by genetic variants at the 17q21 locus, an asthma associated locus in the GWAS of asthma in children, and with expression of two of the genes at this locus, *ORMDL3* and *GSDMB* in the COAST and the Copenhagen Study on Asthma in Childhood (COPSAC) birth cohorts.[147] It is likely that dysregulated immune responses to viral infections of the airway play an important role in asthma inception. Candidate genes selected for their role in antiviral responses have been identified in association with viral-induced asthma exacerbations and childhood asthma phenotypes.[288] Impaired innate immunity with deficient interferon responses to respiratory viral infections has been previously reported. Studies of airway epithelial cells from children with asthma compared with cells from healthy controls have shown increased susceptibility of the former to HRV infection with increased viral replication, reduced production of interferons, and impaired apoptotic responses,[289] although it is conceivable that the presence of asthma alters cellular immune responses rather than arising as a direct consequence of immune dysregulation.

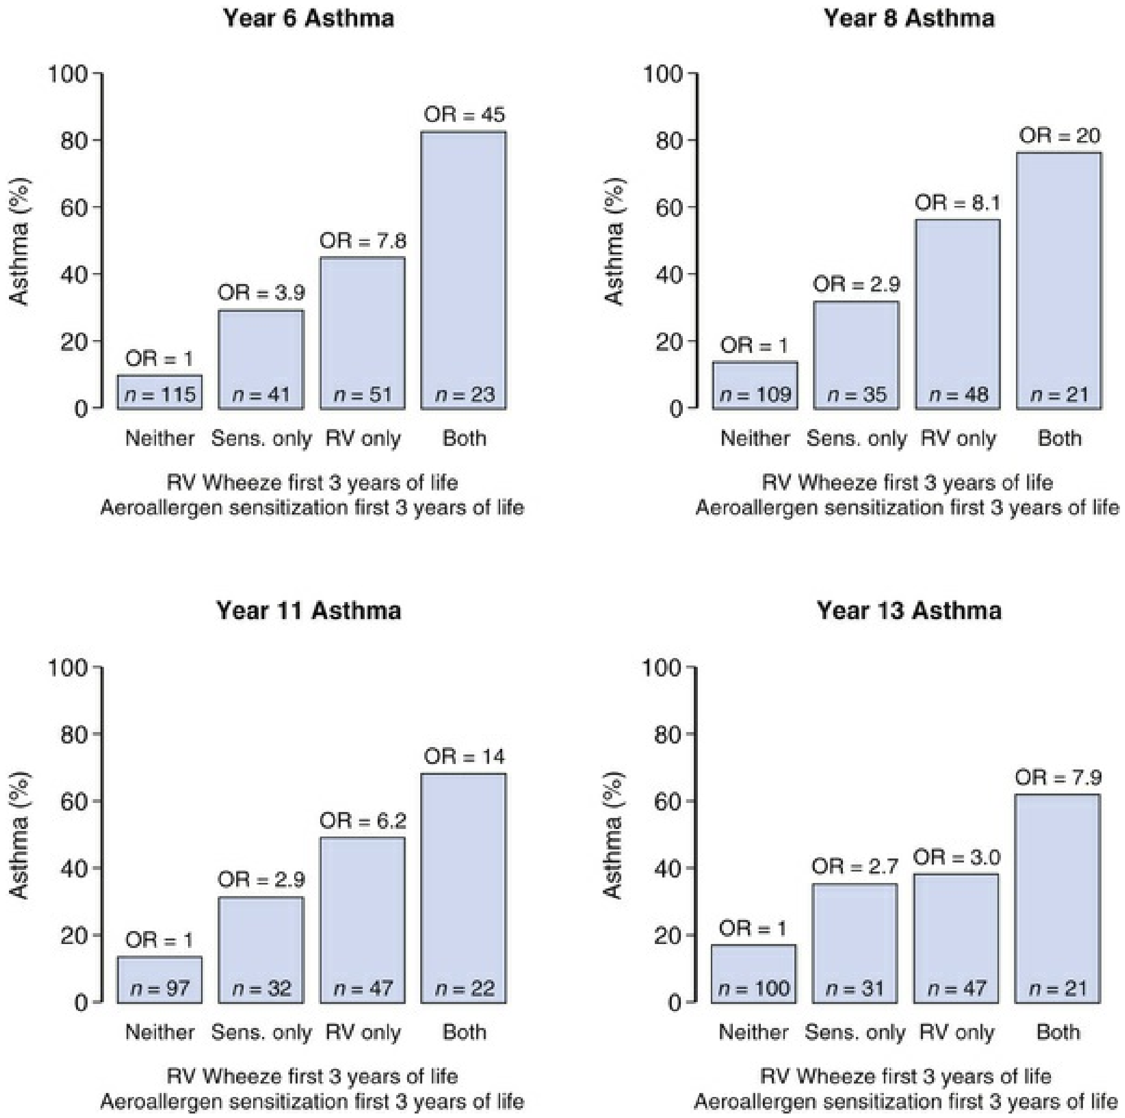

**FIG. 42.5** Both aeroallergen sensitization and rhinovirus (RV) wheezing illnesses in the first 3 years of life increased asthma risk. The effects are additive

and those children with both risk factors had the highest risk between the ages of 6 and 13 years. (From Rubner F, Jackson DJ, Evans MD, et al. Early life rhinovirus wheezing, allergic sensitization, and asthma risk at adolescence. *J Allergy Clin Immunol*. 2017;139(2):501-507.)

The almost exclusive focus on the role of viral pathogens in the respiratory tract in the development of asthma has recently been broadened to the consideration of the role of airway colonization with bacteria.[290] Bacterial colonization of the upper respiratory tract in asymptomatic infants with the pathogenic bacteria, *Streptococcus pneumonia, Haemophilus influenzae* or *Moraxella catarrhalis* was reported to be associated with increased risk for asthma at age 5 years in the COPSAC study.[291] Subsequent evaluation of the mucosal inflammatory response associated with bacterial colonization of the infant airway demonstrated an inflammatory mediator profile indicating a mixed T-helper cell response.[292] Using molecular genetic techniques (*16sRNA* sequencing), the lower airway microbiome, which comprises a very high proportion of organisms that cannot be cultured using conventional methods, has been investigated in adults and children with and without asthma. These showed that the density of bacterial genomes in the lower airways was equivalent to the upper intestine and there were marked differences in the bacterial phyla and genera between asthmatic and healthy airways (Fig. 42.6).[293] The phylum Proteobacteria was overrepresented in asthmatic airways and contains the pathogens, *Haemophilus* spp. and *Moraxella* spp., which were identified in association with asthma in infant airways in the COPSAC study. A number of exposures that could potentially perturb the composition of the airway microbiome have been associated with increased asthma risk in observational studies. These include cesarean section birth (baby not exposed to vaginal microflora), exposure to tobacco smoke,[294] and treatment with antibiotics during early life.[295] However, the causal association of the airway microbiome with asthma inception has yet to be established. Although perturbation of the microbiome offers a plausible explanation for these associations, confounding is an alternative explanation for all observational associations. In the case of antibiotic use, both erroneous treatment of early asthma symptoms with antibiotics (reverse causation) and confounding by indication, where antibiotic use is associated with an independent factor, which is itself associated with increased asthma risk, could explain the observed association.[296]

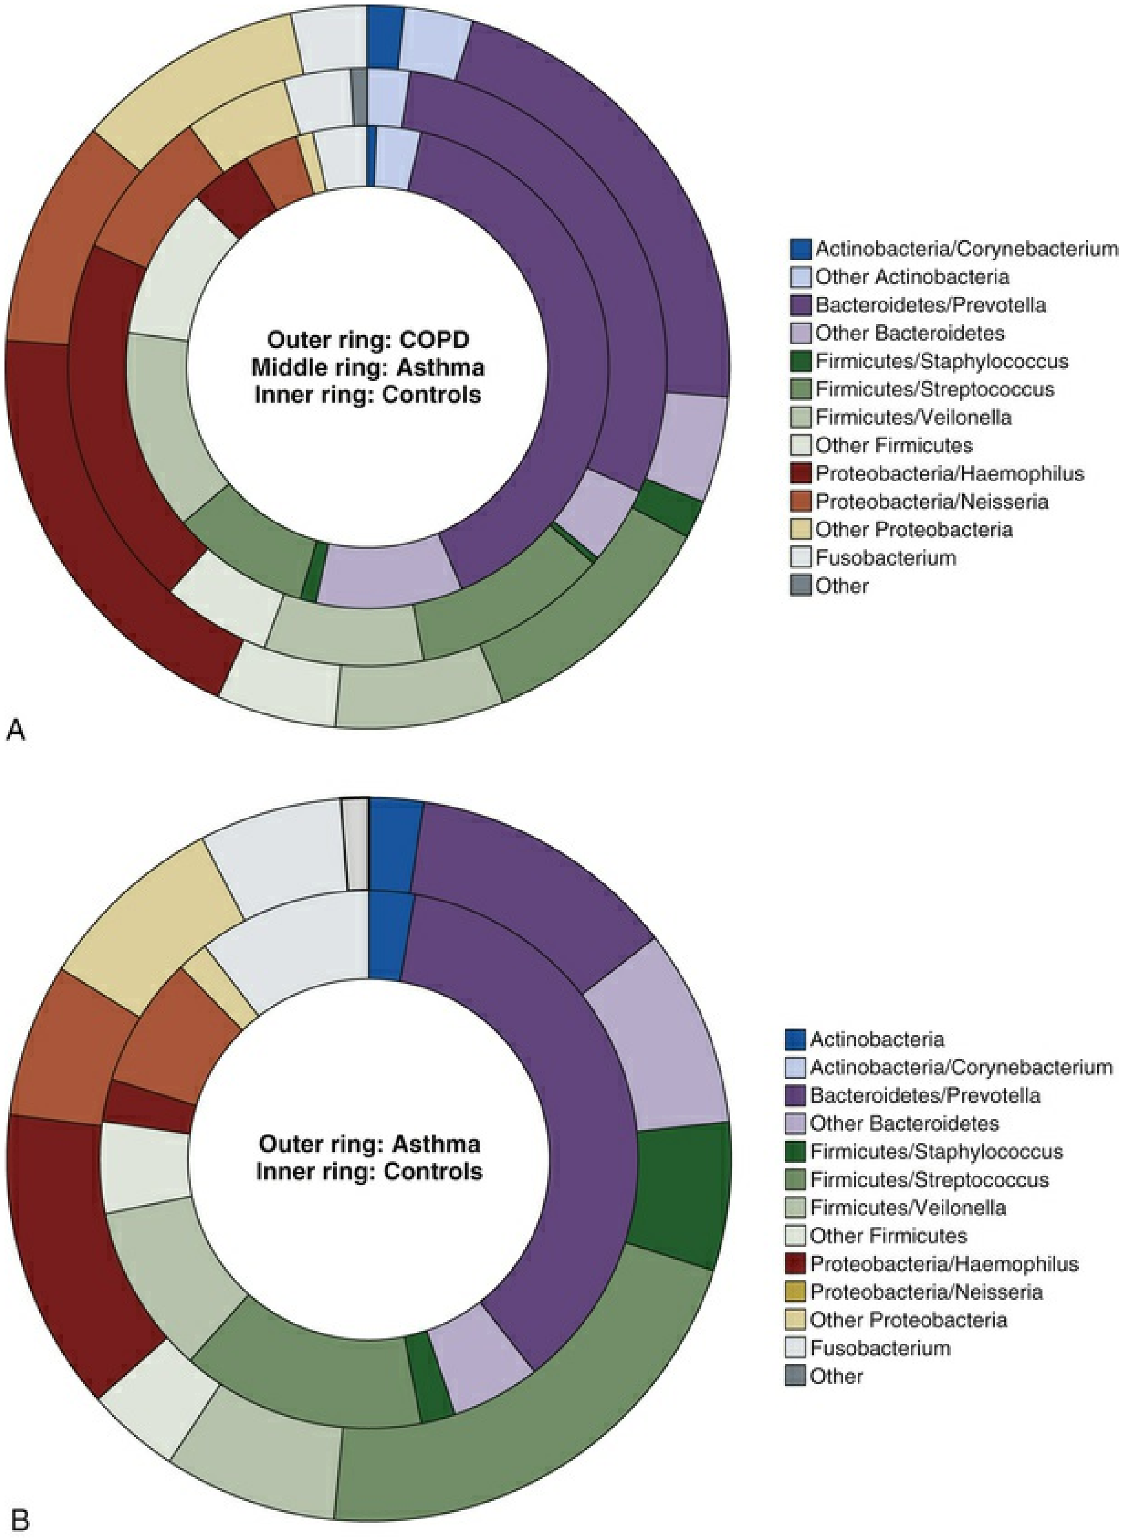

**FIG. 42.6** (A) Distribution of the phyla from sheathed bronchoscopic brushings of the left upper lobe for patients with asthma and COPD, and normal subjects, subdivided into the seven most frequent genera. *(Corynebacterium, Prevotella, Staphylococcus, Streptococcus, Veilonella, Haemophilus, and Neisseria.)* (B) Distribution of the phyla from bronchoalveolar lavage in children with difficult asthma and controls. *COPD,* Chronic obstructive pulmonary disease. (From Hilty M, Burke C, Pedro H. Disordered microbial communities in asthmatic airways. *PLoS One*. 2010;5(1):e8578.)

Helminth infestations are common in many low-income countries where asthma prevalence and morbidity in children is low.[297] It has been suggested that modulation of the host-immune response by helminth infection, which is mediated through Th2 responses, could be protective for the development of asthma and allergies in children.[298] However, although there is some evidence to support a reduction in prevalence of allergic sensitization associated with specific helminth infections,[299–301] there also have been reports of positive associations between IgE sensitization to helminths and increased risk of asthma in children.[302–304] A recent study of coinfection with helminths in poor, urban children in Latin America showed a dose-dependent reduction in aeroallergen sensitization, but no influence on asthma risk.[305]

## Farming Studies

In contrast with studies suggesting a causal role of infections in the etiology of asthma in early childhood, following Strachan's formulation of the hygiene hypothesis in 1989 based on his observations of an inverse association between family size in childhood and subsequent hay fever,[306] there has been interest in the possible protective effect of early infections on the risk of asthma and allergies in children. Farming studies from central Europe and other settings, reported a reduced prevalence of asthma, hay fever, and allergic sensitization in children growing up on farms.[307] The main environmental factors associated with reduced risk of asthma and allergy were contact with farm animals and their foodstuffs, and the consumption of unpasteurized milk, with the strongest effects for exposure during pregnancy and early life. Environmental studies based on the analysis of dust samples from farm residences suggested that increased diversity of microbial exposure compared with reference populations could be the mechanism for the observed protective effect of farm living on asthma in children.[308] Endotoxin, a lipopolysaccharide constituent of gram-negative bacterial cell walls had previously been shown to be inversely associated with allergy in children living on farms, but there were inconsistencies in associations reported between endotoxin exposure and asthma in other settings, including urban environments. A recent study of Hutterite and Amish children in the United States has shed further light on the mechanisms of microbial exposure in farming environments. The Hutterite and Amish share common European ancestry and lifestyles, but have markedly different farming practices; the former living on large-scale, communal, industrialized farms and the latter following more traditional farming practices. They also have striking differences in the prevalence of asthma and allergic sensitization in their children, being around four times higher in the Hutterite than Amish communities.[309,310] This study showed markedly higher endotoxin levels in dust from Amish homes accompanied by differences in innate immune profiles between the two populations, suggesting that microbial exposure in the Amish acted through innate immune targets to decrease asthma risk in this population.[23]

## Physical Activity

Exercise is well recognized as a common trigger for wheeze in children with asthma but the relationship between habitual levels of physical activity and asthma inception is less clear. There is also a complex relationship between physical activity, obesity, and asthma.[311] The contemporaneous rise in asthma prevalence and the move to more sedentary leisure pursuits in children has led to a suggestion that low levels of physical activity or changes in breathing patterns associated with long periods of sitting could influence asthma development.[312] Some studies have reported associations of low levels of physical activity in children with asthma, but the measurement of exposure is problematic; self-report diaries of physical activity are notoriously inaccurate although they remain the dominant instrument in epidemiologic surveys. Objective measurements of heart rate and movements have their own problems, including participant burden, suitability for all forms of physical activity, such as swimming and cycling, and interpretation of the resulting metrics.[313] It is likely that some of these problems inherent in measuring physical activity will be overcome in future with developments in smart technology. One form of physical activity that has received particular attention is swimming, due to the putative risk associated with exposure to products of water chlorination for disinfection.[314] Although there is some evidence to suggest an increase in new-onset asthma in children exposed to chlorinated pools, swimming training for children with asthma appears to be well-tolerated and is not associated with the worsening of asthma control.[315] Physical training has been suggested to reduce airway inflammation in asthma and therefore to be of potential therapeutic benefit. A systematic review of studies that measured airway inflammatory markers after a period of physical training noted generally small sample sizes and substantial heterogeneity in the prescribed interventions and in the methods used to measure airway inflammatory responses.[316] Therefore, although there was some evidence to support a beneficial effect of physical training on airway inflammation, it was inconclusive. A further systematic review of exercise training in children with asthma concluded that it was well tolerated, but there was no evidence to support beneficial effects on asthma control, bronchial responsiveness, and airway inflammation.[317] There is no current evidence that physical training improves lung function in children with asthma, but it does increase aerobic capacity and may be associated with overall benefits in health-related QoL.[318] One caveat to the potential benefits of exercise in childhood asthma is the observation from the Southern California Children's Health Study (CHS) that asthma incidence associated with air pollution (ozone) exposure was modified by physical exercise; and children that participated in more team sports and spent more time outside had higher asthma incidence, but only in areas of high ozone exposure.[319]

# Air Quality

## Outdoor Air Pollution

Since the seminal report of increased asthma and allergies in West German children compared with their peers from East Germany after reunification in 1990,[18] there has been a great deal of interest in the concept that air pollution, particularly from traffic-related sources of fossil fuel combustion, could contribute to the development of asthma in children. Like many observational associations, an argument has raged over whether traffic-related pollutants are causal risk factors for asthma or triggers for asthma symptoms, compounded by the problems of socioeconomic confounding, as children in deprived urban neighborhoods are likely to be exposed to higher levels of air pollution than those in more affluent areas.[320] Advances in geospatial modeling methods with greater resolution have added considerably to the ability to study longitudinal exposure to air pollution at an individual rather than an ecological level in large, unselected population cohorts[321] in which some of the problems of confounding and effect modification can be addressed. Technological advances will soon facilitate meaningful personal exposure monitoring and the ability to incorporate individual activity patterns to modeled estimates of microenvironmental exposure levels. Evidence is now beginning to emerge that air pollution exposure is causal in the development of asthma in childhood.[322] A report by the British Royal College of Physicians has reviewed the evidence for long-term effects of air pollution on health throughout the life course with an emphasis on exposure during the early years of life (https://www.rcplondon.ac.uk/projects/outputs/every-breath-we-take-lifelong-impact-air-pollution),[323] and a detailed review of the evidence of the health effects of air pollution has been published by the WHO with a focus on the impact on policy making in Europe (http://www.euro.who.int/en/health-topics/environment-and-health/air-quality/publications/2013/review-of-evidence-on-health-aspects-of-air-pollution-revihaap-project-final-technical-report).[324] Also, there is evidence that the exposure of pregnant women to air pollution can be associated with increased asthma risk in children (see section "Maternal Lifestyle and Environment," p. 654) and with low lung function in the newborn, which, in turn, increases the risk of early respiratory symptoms and is associated with later asthma.

Traffic-related air pollution comprises a range of toxic gases and particulate matter (PM). Due to the cost and bulk of personal exposure monitoring for several components contemporaneously, the majority of epidemiologic research has relied on modeled estimates of exposure, which is often linked to the residential addresses of study participants.

Results of these observational studies have been heterogeneous. A systematic review of TRAP exposure in birth cohort studies found evidence that increased longitudinal exposure to $PM_{2.5}$ and black carbon was associated with an increased risk of asthma. Different methods were used to estimate exposures, the most common being land-use regression (LUR) but including dispersion models, passive sampling, and the distance of the residence to the main roads. These results were consistent with a recent US study showing that long-term exposure to TRAP from birth to 7 years estimated from LUR models was associated with asthma.[325] However, a large, European, multicenter collaboration that modeled six traffic-related pollutants ($NO_2$, nitrogen oxides [NOx], $PM_{10}$, and $PM_{2.5}$, coarse particulates and $PM_{2.5}$ absorbance) also using LUR in five birth cohorts found no associations with asthma prevalence for any of the pollutants considered.[326] The Pollution and the Young (PATY) project in Europe and North America found no associations of annual average $PM_{10}$ concentrations[327] or $NO_2$ levels[328] with asthma or lung function. The ISAAC study also found no strong evidence of associations between modeled annual, city-level estimates of $PM_{10}$ exposure and asthma outcomes in children, although it was acknowledged that these exposure estimates were likely to be imprecise.[329] In contrast, the US and Puerto Rican GALA II and SAGE II studies, using fixed monitoring sites to measure annual average exposures to ozone, $NO_2$, sulfur dioxide ($SO_2$), $PM_{10}$ and $PM_{2.5}$ reported early-life exposure to $NO_2$ was associated with asthma risk in Latin and African-American populations.[330] Also, using fixed monitoring sites, a Chinese study has shown that early life exposure to $NO_2$ and $SO_2$ was associated with increased asthma risk in children.[331] Clearly, there are differences in both the methods of estimating pollution exposures and in the populations and settings in which these studies were conducted. Gene–environment interaction studies have recently been done to attempt to identify populations at risk of air pollution effects. The traffic asthma and genetics (TAG) study found an association between $NO_2$ exposure and asthma risk in children with minor alleles in the *GSTP1* gene.[154] A meta-analysis of 19 studies of TRAP exposure in children reported that high levels of $NO_2$, nitrous oxide ($N_2O$), and carbon monoxide (CO) were associated with an increased risk of prevalent asthma in childhood, and $NO_2$ was associated with new-onset asthma.[332] Taken together, there is certainly evidence to support early life exposure to TRAP being associated with new-onset respiratory symptoms and asthma in children, although there remains some doubt about whether there is a specific component of relevance with evidence of positive associations for both gaseous and particulate exposures. Recent evidence suggests that exposure to diesel exhaust particles (DEP) results in accumulation of TH2/TH17 cells in the airways, providing an environment that predisposes towards the development of allergic asthma.[333] Exposure to DEP has also been associated with early sensitization to aeroallergens in children,[334] which may interact with viral respiratory illnesses in the developmental pathway of asthma. An increase in the proportion of diesel vehicles in Europe, although not in the United States or Japan, combined with technological difficulties in reducing their real-world emissions of PM and $NO_2$, has meant that urban levels of these pollutants have not fallen as quickly as hoped, to meet European clean air legislation standards.

The effect of exposure to gaseous pollutants, CO, $SO_2$ and $NO_2$ measured at the closest monitoring site to residential address was studied in children with asthma in the US CAMP study and was found to be associated with worsening lung function and increasing bronchial responsiveness.[335] There is also evidence for increased systemic markers of inflammation in children with asthma exposed to high levels of $NO_2$ in two German cohorts.[336] Living close to main roads was associated with an increase in the risk of asthma attacks in an Italian study[337] and TRAP exposure from LUR model estimates was associated with hospital readmissions for asthma or wheezing in a US cohort, but only in white American, not African-American, children.[32] The association between asthma hospital encounters and ambient levels of ozone and $PM_{2.5}$ were stronger in areas with higher-than-median traffic-related sources of pollution in a US study.[338] The evidence that traffic-related exposures could exacerbate asthma symptoms prompted a study in the UK to investigate the effects of an intervention designed to reduce urban air pollution exposure—the London Low Emission Zone (LEZ). However, during its first 3 years of operation, there was no evidence that the LEZ had led to a reduction in either ambient air pollution levels or the prevalence of respiratory symptoms in 8- to 9-year-old school children.[339]

Although traffic-related pollution is a major concern in HICs, the rise in asthma prevalence in rapidly industrializing LMICs has been accompanied by an increase in the contribution to ambient pollutant levels of industrial processes,[340] including fossil-fuel-fired power stations, waste incineration, and agricultural emissions, plus a greater reliance on coal combustion, which is a major emitter of gaseous and particulate pollution.[341] A cross-sectional study in Brazil found increased respiratory symptoms in children living downwind of a petrochemical plant, despite ambient levels of several pollutants being consistently lower than regulatory limits.[342] Similar results have been reported for children living near a petrochemical plant in Spain.[343] Therefore, industrial sources of air pollutants remain an important consideration for asthma inception in industrializing nations and contributing to asthma morbidity worldwide. Industrial sources also contribute to indoor air pollution in developing countries.[344]

There is increasing interest in the relationship of the built environment with human health and residential green space, and increased biodiversity has been suggested as a possible health benefit, although previous studies of asthma have been conflicting. In a Spanish study, green space was associated with a lower prevalence of obesity but not of asthma, although, conversely, living close to a park was associated with asthma but not with obesity.[345] In a population-based cohort of preschool children in British Columbia, residential access to green space was associated with a lower risk of incident asthma, which was enhanced in models that included air pollution exposure.[346] In contrast, a Lithuanian study found that residential greenness was associated with a small increase in asthma risk in 4- to 6-year-old children.[347] A multicenter study of five cohorts from Europe and North America reported differential associations between centers of residential greenness with aeroallergen sensitization by 10–12 years and with no strong evidence of an overall effect.[348] Therefore, the evidence for a beneficial or harmful effect of residential green space on asthma and allergy risk in children remains to be determined; it has potential benefit through increased biodiversity, but also can increase seasonal aeroallergen exposure in the immediate environment.

### Indoor Air Quality.

Young children spend a large part of their time indoors, especially in temperate and cold climate countries. The contribution of air quality to asthma risk and asthma control has tended to focus on the outdoor environment, but the realization that early life exposure is such a critical period for the development of asthma and related illnesses makes the indoor environment an important factor in asthma inception. The most well-established risk factor for asthma in young children is exposure to tobacco smoke with a major contribution coming from exposure in the prenatal period.[185] Second-hand smoke (SHS) exposure in the postnatal period is associated with increased asthma morbidity. A meta-analysis of 25 studies showed that children exposed to SHS were almost twice as likely to be hospitalized for asthma and suffered more emergency room and urgent care visits than nonexposed children with asthma.[349] The introduction of smoking bans in many legislatures caused initial concerns that smoke-free workplaces and public spaces might paradoxically increase children's exposure in the home. However, this was not borne out in practice. Smoke-free legislation has been associated with a reduction in SHS and improved indices of asthma morbidity in adults[350] and children.[351] Hospital admissions for asthma in English children fell after the introduction of national smoke-free legislation[57] and a systematic review of the impact of smoke-free legislation on children's health, including studies in Europe and North America, showed an overall reduction in hospital attendances for asthma of around 10%.[352] In a Chinese study of multiple factors in the home environment in early childhood in relation to new-onset asthma, smoking was identified as a risk factor, although this may have been linked to prenatal exposure that was not assessed. Other features of the home environment in the first 2 years that were associated with later asthma were molds and poor air quality as judged by questions on dryness and odor of the indoor air.[353] Residential indoor molds and dampness have been associated with increased asthma risk in meta-analyses and with asthma exacerbations in both adults and children.[354] However, a Swedish study quantified culturable fungi in dust from the homes of children with asthma and allergies, and healthy controls, and found no associations between fungal concentrations and any health outcomes.[355] A review of other measured microbial factors in the indoor air confirmed only suggestive associations, despite clear observational evidence of an association between asthma and the reported presence of molds and dampness.[354] The ISAAC study also confirmed a link between questionnaire reports of molds and dampness and increased risk of prevalent wheezing in 8- to 12-year-old children in both affluent and nonaffluent countries unrelated to atopy.[356] A recent study used structural inspection of the home at age 5 months in a birth cohort to confirm evidence of moisture damage and found a positive association with asthma at 5 years.[357]

Sources of combustion in the home to provide heat and cooking have been recognized for a long time as emitters of indoor pollutants that might be associated with respiratory symptoms in young children. There is considerable evidence from developed countries that gas stoves used for cooking or heating are associated with an increased risk of asthma in children. Gas stoves are a source of particulate matter and NOx. In a cross-sectional study of participants in the NHANES III Examination, the ventilation characteristics of gas stoves were evaluated. Children in homes that reported using ventilation when the gas stove was in use had a lower risk of asthma and higher lung function values than those where ventilation was either not available or not used.[358] From a worldwide perspective, biomass combustion is a common fuel for cooking and heating in low-income countries, and has a high burden of mortality and morbidity.[359] A systematic review of biomass smoke exposure of women and children found evidence for an increased risk of acute respiratory tract infection, but not asthma, in children.[360] A subsequent cross-sectional study of 5- to 11-year-old children in Nigeria confirmed a lack of association of lifetime asthma risk and evidence of airway obstruction associated with the daily use of firewood compared with a lower frequency of exposure.[361]

A further source of indoor atmospheric pollutants that has been linked to asthma risk is derived from volatile organic compounds (VOCs); a range of chemicals that enter the breathed environment through evaporation from common domestic products, such as cleaning agents, air fresheners, cosmetics, furnishing fabrics, plus paint and floor and wall coverings (https://www.epa.gov/indoor-air-quality-iaq). Most exposure to VOCs occurs indoors as a result of numerous emission sources, low ventilation rates, and the length of time spent indoors, especially in homes.[362] A systematic review of observational and intervention studies of VOCs and the risk of asthma and allergy concluded that the evidence base was of poor quality with inconsistent results.[363] The most frequently studied VOCs in relation to children's asthma are aromatic compounds, such as benzene, toluenes, xylenes, and formaldehyde. A systematic review of formaldehyde exposure and childhood asthma suggested a positive association, but this was largely based on cross-sectional data.[364] Benzene has been suggested to adversely affect respiratory health, including asthma, in children, but the diversity of study design in a systematic review meant that definitive conclusions could not be drawn.[365] Studies of the effects of VOC exposure on asthma symptoms have been beset by similar methodological heterogeneity as the studies of associations of VOCs with asthma prevalence or incidence. For example, a systematic review of exposure to paint fumes in domestic (as opposed to occupational) settings suggested a possible association with wheezing in children, but variations in exposure assignment and study design made it difficult to determine if this particular exposure could cause or exacerbate asthma symptoms.[366] The overall synthesis of evidence, while suggestive of an adverse effect of VOCs on the development and exacerbation of asthma in children needs to be confirmed in well-designed, prospective studies.

## Allergy, Asthma, and the Allergic March

Asthma in childhood is commonly associated with allergic sensitization, and in epidemiologic studies, evidence of allergic sensitization, either through skin prick or specific serum IgE testing, is often used to distinguish between atopic and nonatopic asthma. Atopic asthma, particularly when accompanied by evidence of multiple sensitizations, is associated with onset in childhood, increased risk of severe exacerbations, and poorer long-term prognosis.[367] Asthma clusters within families with other diseases that have an allergic basis,[368] including eczema and allergic rhinitis, and the rise in asthma prevalence experienced in industrialized nations towards the end of the 20th century, were accompanied by an increased prevalence of other allergic conditions.[369] These observations gave rise to the notion of the allergic march; a temporal progression of allergic diseases through early childhood.[370] However, despite their shared characteristic of allergic sensitization, much of the circumstantial evidence for the allergic march was derived from repeat cross-sectional studies. Recent analysis of longitudinal data from birth cohorts indicates that the allergic march is the exception rather than the rule in children with early onset of one of these conditions, usually eczema.[371,372] The situation is probably complex as specific genetic associations with the asthma–hay fever phenotype that are distinguishable from GWAS hits for asthma alone have been identified.[142] This fits with emerging evidence that allergic asthma in children is not a single phenotype, but comprises several subphenotypes.[374] Concepts of allergy are also evolving, and the reductionist approach of assigning allergic status on the basis of defined “positive” thresholds of skin or serological tests is now anachronistic. More sensitive and precise methods allow better quantitation of the strength of the allergic response,[375] component resolved diagnostics enable responses to different epitopes to be identified,[376] and new analytical methods that group responses to allergen classes have been developed. Applying a machine learning approach for analyzing longitudinal repeat assessments of allergic sensitization in a birth cohort led to the identification of different latent patterns of allergic sensitization,[377] which were replicated in an independent cohort.[378] Multiple, early sensitization had a substantially stronger association than conventional classification of atopy with asthma and with markers of asthma severity. The evidence that monosensitization and polysensitization carry different risk profiles combined with novel approaches to classification of disease are now being integrated with "-omics" data in systems biology models of disease in a bid to increase the understanding of allergy and its relationship with disease manifestations.[379]

The importance of allergic sensitization to asthma inception inevitably raises the question of whether allergen exposure in early life is an important step in this process. However, although allergen exposure is a prerequisite for sensitization, the evidence from observational and intervention studies suggests a complex interplay between the dose, timing, and route of allergen exposure, the presence of coexposures, and the genetic predisposition of the individual in the development of allergic diseases.[380] Allergen avoidance was shown to be ineffective in reducing respiratory symptoms in children up to 3 years of age, but increased dust mite sensitization in the intervention group in a highly effective dust mite avoidance study in a high-risk population of infants.[381] Therefore, different approaches to primary prevention of allergic sensitization and prevention of progression to asthma are required.[382] These might include the therapeutic application of allergen[383] and the blocking of host responses,[384] some of which have been tested in proof-of-principle studies pending larger scale trials.

## Conclusions

Epidemiology has been remarkably successful in tracking change in the prevalence of asthma over time and geography, particularly through collaboration in large-scale international studies, such as ISAAC. These studies, in turn, pointed to variations in the environment and lifestyle that were associated with greater or lesser prevalence of asthma. The recognition of early life events as being fundamental to asthma etiology prompted the development of birth cohorts, some of which were recruited in pregnancy and were well placed to study antenatal as well as postnatal influences. These have been instrumental in developing ideas about phenotypic variation in asthma and in studying the associations of environment on the risk of developing the disease. However, despite enormous efforts, few risk factors were identified that had more than modest evidence of association, and the establishment of causality was not possible, even with stringent attention to the sources of bias, confounding, and measurement error. New approaches to epidemiologic analysis are starting to address some of these problems, but proof of causal association still relies on experiments. The advent of high throughput methods for genomic and other-omic assays moved asthma genetics beyond the field of candidate gene discovery to agnostic genome-wide associations, which have indicated novel genetic regions that are associated with asthma and which have been replicated in independent studies. Attention is now shifting from gene discovery to the investigation of gene–gene and gene–environment interactions, and to the modification of genetic effects through epigenetic mechanisms that form a bridge between the environment and genetic expression. The jury is still out on whether heritable epigenetic marks are important in explaining some of the high heritability of asthma that is seen in twin studies. Recent convergence of two important pathways that have long been recognized as being fundamentally important in the early origins of asthma in children has produced new insights into the interplay between allergic sensitization and viral respiratory tract infections, so we are now on the brink of interventions for primary prevention. Therefore, despite the limitations of identifying causal factors in the development of disease that are inherent to epidemiologic study design, epidemiology has made a major contribution to understanding the phenotypic variation of asthma in children, particularly around the critical time when early life respiratory infections progress to asthma. It has also provided insights into how genetic predisposition influences responses to environmental exposures, and which factors in the environment are likely to be important in asthma inception. The generation of massive amounts of data from technological innovations in assaying genetic variation, biomarkers of disease, and environmental factors—and their integration into systems biology models of disease—present new challenges to developing the analytical tools and interpretative strategies necessary for the translation of this new knowledge into patient benefit.

# The Immunopathogenesis of Asthma

*Sejal Saglani BSc, MBChB, MD, Clare M. Lloyd PhD*

The fundamental pathophysiological features of asthma include airway hyperresponsiveness (which can also manifest as reversible airflow obstruction), inflammation, and structural changes in the airway wall, collectively termed airway remodeling. The development of allergic sensitization is also key to the immunopathology of pediatric disease. The combined clinical effects of these abnormalities result in the manifestation of symptoms which include shortness of breath and wheezing, with or without cough.

A key factor that needs to be considered in the immunopathogenesis of pediatric asthma is the age of the child. Wheezing disorders are common in children aged 5 and under, but not all preschool wheezers will develop asthma and the mechanisms mediating preschool wheeze are likely to be distinct from those that result in progression to asthma and drive asthma in school-aged children. A complex interplay between host susceptibility, the developing airway microbiome, environmental insults such as exposure to allergens and pollution, and respiratory infections results in pulmonary immune responses and the pathophysiological features of asthma (Fig. 43.1). The aim of this chapter is to summarize what is known about the immunology and pathology of allergic asthma in children and to highlight specific situations, such as preschool wheeze, asthma exacerbations, and severe therapy resistant asthma, in which this common immunopathology may not apply. The need to focus on approaches to achieve disease modification and asthma prevention in the future will also be discussed.

## Altered Pulmonary Immunity in Asthma Inception

Development of allergic sensitization is a key component of asthma pathogenesis in children. Sensitization may develop to food or aeroallergens and is initiated at mucosal or barrier surfaces where there is an epithelial layer. Respiratory mucosal surfaces (airways) are continuously exposed to inhaled, nonpathogenic foreign particles (antigens, microbes, and pollutants). A key challenge for the healthy respiratory system is therefore to distinguish innocuous antigens from pathological microbes.[1] However, in disease, and with a host underlying susceptibility to allergic disease, an exaggerated immune response is mounted to inhaled allergens. The pulmonary epithelium is the first point of contact and both barrier and immune function of this airway structure is altered in children with asthma.[2,3] The altered bronchial epithelial function results in a "leaky" airway wall and permits entry of antigen (allergen) through the epithelium (Fig. 43.2)[4] with recognition and uptake by the pulmonary antigen presenting cells—dendritic cells (DCs)—that are continuously undertaking surveillance close to the mucosal surface.[5] DC dendrites may protrude through to the airway lumen to undertake antigen recognition via cell surface receptors (see Fig. 43.2). DCs take up the antigen, then migrate to the pulmonary draining (mediastinal) lymph nodes where they present the antigen to naive T cells. The naive T helper (Th0) cells subsequently differentiate to type 2 T helper cells under the influence of inflammatory cytokines such as interleukin (IL)-4. The Th2 cells are then released and migrate back to the pulmonary tissue where, with further allergen exposure, they initiate an allergic reaction characterized by the release of additional allergic inflammatory cytokines including IL-5 and IL-13. In parallel, antigen is presented to B cells in the draining lymph nodes where the antigen (allergen) is processed, and immunoglobulin (Ig)E antibody to the antigen is secreted by B cells and released into the circulation and pulmonary tissue in preparation for a response to future allergen exposure (see Fig. 43.2). IL-4 is necessary to allow the isotype switch of antibody production from IgG molecules to Ig-E molecules in an allergic environment. Allergen sensitization results from the initial allergen exposure, and subsequent allergen exposure results in an allergic reaction. This is characterized by recognition of the allergen (antigen) by Ig-E (antibody), which binds to mast cells and results in mast cell degranulation with release of histamine and leukotrienes and a resulting type 1 immediate reaction (see Fig. 43.2). This is associated with a more chronic allergic reaction that results from induction of Th2 cells and downstream inflammatory mediators including IL-4, IL-5, and IL-13, which are the hallmark of and drive for allergic reactions.

**FIG. 43.2** Development of allergic sensitization and asthma. Inhaled exposures cause barrier dysfunction, which makes the epithelium "leaky" and allows entry of allergens through the airway wall, to be recognized by the pulmonary antigen presenting cells (dendritic cells) for subsequent antigen processing and development of allergic sensitization. Immunoglobulin (Ig)-E antibodies are synthesized by B cells and released into the circulation where they recognize antigen. This is followed by binding to mast cells to release growth factors and mediators results in symptoms of allergy and asthma.

# Cells, Molecules, and Cytokines Involved in Pediatric Allergic Asthma

## Eosinophils and Interleukin-5

Eosinophils are the hallmark feature of the asthmatic immune response in most patients,[6] children in particular. The role of eosinophils in allergic inflammation is summarized in Box 43.1.

**Box 43.1**

### The Role of Eosinophils in the Development of Allergic Inflammation

1. Initiation of events that lead to Th2 inflammation
2. Suppression of Th1 mediated immunity
3. Recruitment of Th2 cells to the lung
4. Release of growth factors that contribute to the development of airway remodeling[7]

*Th,* T helper.

Eosinophils contain multiple granule proteins that exhibit an array of toxic and immune-modulatory activities. The granule proteins can be released by different mechanisms, including during an acute allergic insult, and they cascade the proinflammatory, Th2 responses associated with allergic asthma.[8] The cytokines and chemokines released following eosinophil degranulation promote longevity of eosinophils in tissues, which leads to the cyclical nature of signaling, activation, and survival. Additionally, these proteins target any foreign antigen, promote inflammation in the area, and may cause considerable damage to surrounding structures.[6]

IL-5 is released by Th2 cells in asthma (Fig. 43.3) and results in the induction and recruitment of eosinophils from the peripheral circulation to the airways. IL-5 also promotes eosinophil differentiation, growth, and survival.[9] The airway eosinophilia that is characteristic of pediatric allergic asthma in children is therefore thought to be mediated by IL-5. However, this is an assumption based on extrapolation from animal and adult studies. Firm evidence for the presence of IL-5 in the airways of children with stable asthma is difficult to find. As airway samples are not easily obtained from children, most studies investigating the mediators of allergic asthma include assessments of peripheral blood, but this is not always a reliable surrogate for the airways.[10] Another issue that affects the detection of Th2 cytokines in asthma is that they are steroid sensitive, so it can be difficult to find elevated levels in patients who are not "steroid naïve" and who have been prescribed maintenance inhaled steroids (which is the case for most children long before referral to hospital). However, it remains certain that the predominant airway inflammatory phenotype of pediatric asthma is eosinophilic, and this is independent of disease severity[11,12] or duration.[13–15] Therefore modulating eosinophil function or reducing their numbers has been one of the most important therapeutic goals in asthma for many years. The mainstay of treatment for asthma is inhaled glucocorticoid steroids. Glucocorticoids increase eosinophil apoptosis and block the survival effect of interleukin-5, resulting in a reduction in airway eosinophilia with steroid therapy.[16] Assessment of the receptor for IL-5 on peripheral blood eosinophils from healthy, steroid naïve, and steroid treated asthmatic children has shown reduced IL-5 receptor expression in patients treated with inhaled steroids, and this was concomitant with reduced *in vitro* responsiveness to IL-5.[17] This is therefore a potential mechanism by which steroids inhibit IL-5 in children on maintenance therapy for asthma. Interestingly, children with severe asthma, who are on high-dose maintenance inhaled steroids, have a persistent airway eosinophilia in the absence of detectable IL-5, suggesting that alternative mechanisms contribute to the development of eosinophilia as disease becomes more severe.[11] This has obvious implications for the use of anti-TH2 monoclonal therapy.

## Mast Cells in Asthma

The immediate response during an allergic reaction in a patient with asthma results from binding of allergen-specific Ig-E antibodies to mast cells, and following cross-linking of the allergen across two antibody molecules, the resulting degranulation of mast cells results in a release of mediators that cause the symptoms of bronchoconstriction, airway edema, and inflammation (see Fig. 43.2). The predominant mast cell mediators that are released include histamine and cysteine leukotrienes.[18] Despite the obvious role of mast cells in allergic reactions, their importance in asthma pathogenesis remains uncertain,[19] since treatments that have aimed to prevent or reduce mast cell degranulation, such as sodium cromoglycate and other mast cell stabilizers, have been relatively ineffective in children,[20] and there is little evidence of an increase in tissue mast cells in children with severe asthma.[11] Therapies that have targeted mast cell mediators, such as leukotriene receptor antagonists that minimize the downstream proinflammatory effects of leukotrienes,[21] have also been trialed in children with asthma, but again, their efficacy has been disappointing.[22] It may be that the location of mast cells within specific structures in the airway wall is important in determining their pathological effect. Increased numbers of mast cells have been shown to be present specifically within airway smooth muscle in patients with asthma but not those with eosinophilic bronchitis.[23] Moreover, mast cells have been shown to modulate the function of airway smooth muscle[24] and, via release of Th2 mediators such as IL-13, can result in increased airway hyperresponsiveness.[25] It is therefore likely that only therapies targeting tissue-specific mast cells will prove to be beneficial.

## Lymphoid Cells

### T-Lymphocytes

The key inflammatory cell that is central to driving asthma pathogenesis, and is induced following the development of an adaptive immune response to allergen exposure, is the T-helper 2 (Th2) lymphocyte (see Fig. 43.2). These $CD4^+$ cells express the T-cell receptor and have the capacity to secrete various cytokines depending on their local environment. Th2 lymphocytes are induced following allergen exposure and release hallmark Th2 cytokines including IL-4, IL-5, and IL-13 (see Fig. 43.3), which are considered important in the initiation and development of the pathophysiology of asthma.[26,27] IL-4 is essential for the development of Ig-E and allergic sensitization; IL-5 is an eosinophil growth factor, chemoattractant, and promoter of eosinophil survival; while IL-13 is most closely associated with the development of airway hyperresponsiveness (AHR) and airway remodeling. Although Th2 cells are important in driving allergic airway responses, these are not the only lymphocyte subset involved in asthma pathogenesis. Numerous other T-cell subsets have been implicated in asthma, including Th9 cells and Th17 cells.[26] Effector $CD4^+$ T cells are defined by expression of specific transcription factors, which determine their secreted cytokines. Th2 cells express the transcription factor GATA3 and secrete IL4, 5, 13; while Th17 cells express receptor-related orphan receptor gamma t (ROR-$\gamma$T) and secrete IL-17 (see Fig. 43.3). However, it is also becoming increasingly apparent that the inflammatory environment is central to determining cellular function. A change in milieu can result in a change in cytokine secretory pattern, which is termed T-cell plasticity.[28] In addition, not all T lymphocytes are proinflammatory and pathogenic. There is a critical balance between regulatory and proinflammatory T-lymphocytes that needs to be maintained to prevent disease, and it is proposed that in asthma an imbalance in favor of Th2 cells with a concomitant reduction in T regulatory (Tregs) cells results in disease manifestation.[29] There are two main types of Tregs in the lung: $CD4^+$ cells that secrete the antiinflammatory cytokine IL-10, and $CD4^+CD25^+$ cells that have the transcription factor FoxP3. At present, data relating to the presence of these cells in the airways of children with asthma is scant, but assessment of peripheral blood and bronchoalveolar lavage has shown reduced numbers of $CD4^+CD25^+FoxP3^+$ cells in asthmatics compared to healthy children[30,31]; however, these results were from steroid naïve patients. It is interesting to note that treatment with inhaled steroids results in higher levels of circulating[32] and airway Tregs, but the cells remain functionally impaired.[31] Children with severe asthma, whose symptoms are not controlled despite high-dose steroid therapy, have significantly lower levels of airway IL-10 and have a significantly reduced capacity for secreting IL-10 from circulating peripheral blood $CD4^+$ T cells,[33] suggesting relatively steroid resistant disease is characterized by a poor induction of IL-10 secretion from $CD4^+$ cells after steroid therapy.

## Innate Lymphoid Cells

Until recently, the predominant immune response that was thought to drive allergic asthma was an adaptive response mediated by Ig-E and T lymphocytes. However, it is now apparent that innate immunity plays a significant role in asthma pathogenesis. Murine experimental models have demonstrated the release of innate cytokines from the airway epithelium in response to allergen. These cytokines include IL-33, IL-25, and thymic stromal lymphopoeitin

(TSLP).[34] Of these, IL-33 has more specifically been associated with the onset of allergic immune responses by the induction of a group of cells called innate lymphoid cells (ILCs) (Fig. 43.4).[35] ILCs are of comparable size and morphology to T lymphocytes, but lack the T-cell receptor and surface markers, such as CD3/CD4/CD8 that are the hallmark features of T cells (Table 43.1). The importance of the innate cytokines and ILCs in initiating pediatric asthma remains uncertain, but IL-33 is likely to be important in mediating severe therapy resistant asthma since it promotes airway remodeling and is relatively steroid resistant.[36] Subpopulations of ILCs are induced depending on the stimulus and environment in a similar manner to T cell subtypes.[37] Group 2 ILCs (ILC2s) that secrete the Th2 cytokines IL-4, IL-5, and IL-13 are therefore induced by IL-33 upon allergen exposure. There is evidence for increased numbers of ILC2s in the airways of children with severe asthma compared to controls,[38] but their functional role in mediating disease and relative importance compared to T lymphocytes in pediatric disease remains unknown. Importantly, it is becoming increasingly apparent that an equal interplay between both ILCs and T cells is essential in initiation and persistence of disease,[39–41] and it is unlikely that only one cell type is predominant.

*Ig*, Immunoglobulin; *IL*, interleukin; *TSLP*, thymic stromal lymphopoeitin.

### Neutrophils

Neutrophils are thought to be important in mediating severe asthma in adults[42] and it is proposed that dampening down neutrophilic inflammation may be beneficial. However, their role in pediatric disease is far less clear. There is no convincing evidence of increased airway mucosal neutrophils in children with asthma during stable disease.[11,43,44] However, neutrophils are increased during exacerbations that are precipitated by infection, suggesting they may not be pathogenic, but an important response in clearing infection. There is recent evidence showing a subgroup of children with severe asthma have increased neutrophils specifically within the airway epithelium, and contrary to expectation, those with intraepithelial neutrophils had better lung function, symptom control, and were on lower doses of maintenance inhaled steroids.[43] Therefore at present, blocking or reducing neutrophils cannot be recommended as an important therapeutic strategy for children with asthma, as they may indeed be beneficial. The role of neutrophils in the specific case of wheezing in preschool disorders is discussed below.

## School-Age Allergic Asthma: Pathology and Mechanisms

Asthma is a chronic inflammatory airway disease, which in children is characterized by a predominance of eosinophils in the airway wall and lumen.[45] Evidence of eosinophilia has been confirmed in endobronchial biopsies[13,46] and broncho-alveolar lavage[12] from school-aged children regardless of disease severity.[11] The inflammation is accompanied by the presence of structural airway wall changes, or airway remodeling (Fig. 43.5). These changes are thought to be inappropriate to maintain normal lung function.[47] However, there is some evidence that certain structural changes, increased thickness of the reticular basement membrane in particular, may be protective as they provide reduced airway collapsibility.[48] The specific structural airway changes present in children with asthma include increased thickness of the subepithelial reticular basement membrane (RBM),[13,49] increase in both size and quantity of airway smooth muscle (Fig. 43.6),[11,50] and increased number of vessels (angiogenesis).[13] All of these changes are present by school age regardless of disease severity.[13,49] Certain features, such as thickness of the RBM, are present to the same extent in children as they are in adults with asthma and are therefore also independent of disease duration.

Asthmatic airway wall

**FIG. 43.5** Pathology of allergic asthma: parallel development of airway inflammation and remodeling. Environmental insults including allergens, infection, and pollution result in the pathogenesis of asthma with parallel development of airway inflammation and remodeling. The airway wall structures that are altered in asthma include the airway epithelium, increased thickness of the subepithelial matrix, and increased smooth muscle mass. The predominant inflammatory phenotype is eosinophilia.

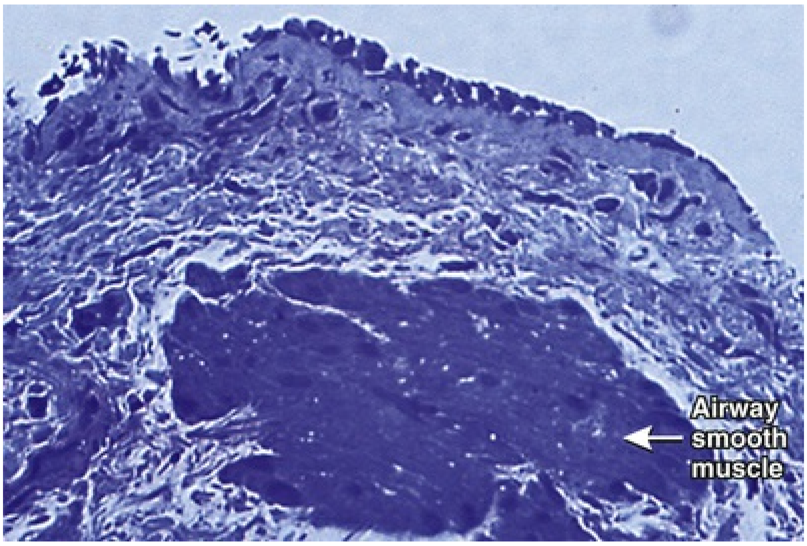

**FIG. 43.6** Endobronchial biopsy stained with toluidine blue showing increased airway smooth muscle mass in a patient with asthma.

It had been proposed that repeated cycles of inflammation resulting from allergen exposure resulted in the development of structural airway changes,[51] however, experiments using a neonatal mouse model[52] and findings from cross-sectional studies that have investigated asthma pathology in children[53,54] have shown that the key pathophysiological changes of allergic asthma (airway hyperresponsiveness, eosinophilic inflammation, and airway remodeling) develop in parallel (see Fig. 43.5). Importantly, this implies that therapies that only target eosinophilic inflammation may be insufficient to achieve optimal disease control and improved lung function in all patients. Targeting eosinophilic inflammation alone, using inhaled steroids, has resulted in improved symptom control and lung function in the majority of children; however, it is apparent that this approach in isolation does not achieve disease modification, specifically when used in early onset preschool disease.[55] It is now accepted that the airway structural cells are not just altered in quantity in asthma, but they are immunologically active and have a fundamentally altered functional phenotype which contributes to asthma pathogenesis as well.[56]

## The Clinical Relevance of

# Eosinophilic Inflammation in School-Age Asthma

## Stability of Eosinophilic Inflammation in Pediatric Asthma and Impact on Therapy

Although pediatric asthma is predominantly an eosinophilic condition, the inflammatory profile is heterogeneous between patients. The predominant pattern of airway inflammation has been used to define and subdivide patients with asthma according to inflammatory phenotypes. These include eosinophilic, neutrophilic, pauci-granulocytic (no inflammation), or mixed.[57] However, it is recognized that the inflammatory phenotype may not remain stable over time in the same patient. One reason for a "switch" in inflammatory phenotype is the development of an acute respiratory infection, which may change the profile from predominantly eosinophilic to neutrophilic or mixed. However, intriguingly, in children with asthma, change in airway inflammatory phenotype can be documented over time independently of exacerbations, symptoms, disease manifestation, or alteration in therapy.[58] Therefore a possible explanation for eosinophil directed therapy being unsuccessful in children[59] may be the impact of phenotype switching, or indeed, a less important functional role of eosinophils in causing disease pathogenesis in children compared to adults. The differences between eosinophil targeted therapy in adults and children highlights the importance of investigating disease mechanisms in age appropriate experimental models and not undertaking direct extrapolation of data from studies in adults to children.[60] In addition, these findings question whether novel therapies that are targeted to a reduction in levels of IL-5 (monoclonal antibody to IL-5 or its receptor) and thus a specific reduction in eosinophils will be beneficial in children. Mepolizumab (monoclonal antibody to IL-5) has proven to be effective in reducing exacerbations in adult eosinophilic asthma,[61] but efficacy data in children are awaited, and are mandatory before these therapies are offered to children.

## Noninvasive Biomarkers of Eosinophilic Inflammation

Much effort has been undertaken to find a noninvasive objective biomarker to assess the efficacy of inhaled steroids in reducing airway eosinophilia as a guide to monitor disease and tailor treatment.[62] Several biomarkers have been investigated in pediatric allergic asthma. One of the first was serum eosinophilic cationic protein (ECP), a mediator that is released by eosinophils when they are activated. It has been shown that ECP is steroid sensitive and therefore is reduced following treatment, and levels are closely related to peripheral blood eosinophils,[63,64] but there is little evidence to show ECP levels relate to airway eosinophil numbers or activation status, meaning serum ECP adds little as a biomarker over peripheral blood eosinophil counts, and it is therefore not used to monitor disease. Another issue that complicates the use of eosinophil biomarkers measured in the peripheral circulation and not in the airways in asthma is that other allergic conditions may also be associated with elevated levels. For example, children with atopic dermatitis, whether or not they have asthma, may have elevated ECP, and blood eosinophils. It is therefore important to interpret results, specifically of peripheral blood biomarkers, with some caution.[10]

A biomarker that has been extensively investigated more recently is exhaled nitric oxide (FeNO). It is associated with airway eosinophilia in children with difficult asthma[10,65] and therefore considered a better noninvasive marker than serum ECP or total eosinophils. Reference values for normal levels are also available for children of all ages.[66] FeNO is useful to support a diagnosis of asthma in steroid-naïve patients, although it can be elevated in atopic, nonasthmatics.[67] It is very steroid sensitive, and in children it has been repeatedly shown to be no better than clinical parameters alone to monitor disease control.[68,69] A recent systematic review of the accuracy of currently available noninvasive biomarkers to detect airway eosinophilia has shown only moderate diagnostic accuracy of exhaled nitric oxide in correctly detecting airway eosinophils, so the use of this alone as a biomarker would lead to a significant number of false positives and false negatives.[70]

In addition, longitudinal relationships between FeNO and sputum eosinophils vary over time within the same patient regardless of clinical status.[71] The steroid sensitivity of FeNO can be used as a very reliable surrogate assessment of adherence to inhaled steroids, whereby a significant fall in FeNO was observed in all previously nonadherent patients after a period of directly observed therapy.[72]

# Essential Role of Structural Airway Cells in Pulmonary Immunity and Asthma Pathogenesis

## Pulmonary Epithelium

Until recently, it was thought that the function of the airway epithelium was simply to act as a passive barrier to prevent the entry of particles such as allergens, pathogens, or pollution into the airway wall. However, it is now known that the pulmonary epithelium is not just a barrier, but is also immunologically active and is central to the development of immune responses involved in the pathogenesis of asthma.[73] Cultured primary bronchial epithelial cells from children with asthma have dysregulated functional capacity to repair wound injury.[3] In addition, responses to rhinovirus infection of epithelial cells from children with asthma are impaired, whereby production of the antiviral cytokine interferon-β is reduced and epithelial repair following infection is delayed.[74,75] There are significant differences in release of mediators from bronchial epithelial cells following exposure to a range of proinflammatory stimulants including IL-1β, IL-4, and IL-13 between children with and without asthma.[76] The functional importance of the airway epithelium is also reflected in findings from genome wide association studies (GWAS) of asthma susceptibility genes. The majority of genes that are associated with a high risk for asthma, specifically in children, such as interleukin-33, protocadherin, and CDHR3, are expressed in the pulmonary epithelium.[77] This suggests that altered airway epithelial function is central to asthma pathogenesis. Several SNPs in the ORMDL3 gene located on chromosome 17q have been shown repeatedly to be associated with asthma that develops following recurrent infection with rhinovirus in the preschool years.[78,79] Thus, future studies that manipulate pulmonary epithelial function by altering the expression of these susceptibility genes may uncover novel therapeutic targets that may allow restoration of epithelial function in patients with asthma.

An important immunological function of the airway epithelium in asthma and other chronic inflammatory airway diseases is its ability to secrete cytokines in response to various stimuli. The role of the innate epithelial cytokines in initiating allergic airway responses and in the pathogenesis of asthma is currently being extensively investigated as a pathway that may lead to novel therapies. Exposure of the bronchial epithelium to allergens, infections, and pollutants in patients with asthma is thought to result in the direct release of three key innate cytokines, IL-33, IL-25, or TSLP (see Fig. 43.4). The actual cytokine released is determined by the environmental exposure and the host susceptibility.[34] The airway epithelium thus provides an innate mechanism of initiating immune responses, without the need for adaptive immunity via antigen-presenting cells, allergen sensitization, and Ig-E production. The downstream effects of the innate cytokines are to induce ILCs, which have the capacity to function in the same way as T helper 2 cells with secretion of the type 2 cytokines IL-4, IL-5, and IL-13 (above). This key role in disease initiation has put the pulmonary epithelium at the center of asthma pathogenesis and it is a key tissue whose function is being extensively investigated to allow the discovery of novel therapeutic targets.[56]

## Airway Smooth Muscle

In an analogous manner to the epithelium, it is known that stimulation of airway smooth muscle does not simply result in contraction, as it is an immunologically active component of the airway wall. There is extensive cross-talk and interaction specifically between mast cells and the airway smooth muscle in asthma (see above section on mast cells). Although the function of airway smooth muscle has been investigated in adult asthma, very little is known about its function in children with asthma. This is an important area for future research since significant evidence suggests that early alterations in smooth muscle function is one of the best predictors of development of asthma from preschool wheeze (see Fig. 43.6).[80]

# Preschool Wheeze: A Unique Maturing Immune Environment

## Phenotypes of Preschool Wheeze and Response to Currently Available Antiinflammatory Therapies

An important clinical phenotype that is very distinct and unique to children is that of wheezing in preschool children. Cohort studies have shown that there are several clinical phenotypes of wheezing in preschool children with different outcomes by school age.[81] However, these phenotypes can only be applied retrospectively after the child is 6 years old. Prospective clinical phenotypes have therefore been defined by the European Respiratory Society.[82] These include viral episodic wheeze, which is characterized by wheezing in discrete episodes with no symptoms in between, and multiple trigger wheeze in which children have symptoms both during and in between acute episodes. Little is known about immunopathogenesis and molecular mechanisms that specifically mediate viral episodic wheeze, but what is known is that usual therapies that are effective in allergic asthma at school age are rarely beneficial in preschool children with viral wheeze. Specifically, during exacerbations, there is no evidence for efficacy of systemic corticosteroids on any clinical outcome measure.[83–86] In addition, leukotriene receptor antagonists confer little benefit during exacerbations of viral induced preschool wheeze.[87,88] These data imply the inflammatory process during acute viral wheezing episodes in preschool children is very different to that in allergic asthma. Recently, it has become apparent that similar numbers of wheezing episodes in preschool children are associated with bacterial infections as with viral infection.[89] The term episodic viral wheeze may therefore be better represented as infection associated wheeze. Furthermore, bronchoscopy studies have shown that the airway inflammatory profile of episodic wheezers during stable disease is either similar to nonwheezing controls[46] or it is predominantly neutrophilic,[90,91] and may be associated with positive bacterial cultures, despite the absence of symptoms.[92] There is therefore increasing data to suggest the pathogens that cause acute episodes of wheezing in preschool children are distinct from those in allergic asthma, and that the underlying immune and inflammatory mechanisms mediating disease are also distinct.

## Airway Inflammation in Infection Associated Preschool Wheeze Exacerbations

In view of the evidence for bacterial infections being associated with preschool wheezing episodes, two recent clinical trials have been undertaken to determine the efficacy of the macrolide azithromycin to treat acute exacerbations. Although both have shown a benefit for their primary outcome,[93,94] the use of azithromycin for acute preschool wheeze cannot be recommended in routine clinical practice, since both trials have significant limitations.[95,96] Neither showed benefit in the most relevant clinical outcome measure of hospitalizations, or need for oral steroids, and neither investigated the mechanism of action of the azithromycin. The efficacy of the macrolide therapy in both trials seemed more likely due to the antiinflammatory effects of azithromycin than the antibacterial effects. Importantly, and worryingly, the trial by Bacharier et al. showed a significant increase in macrolide resistance over the short trial duration.[93] A much clearer picture of the airway inflammatory profile during both stable disease and exacerbations in preschool wheezers is therefore needed, with an aim to targeting specific inflammatory and infective phenotypes to achieve more effective treatments.

## Airway Pathology in Preschool Wheezers With Symptoms During and in Between Exacerbations

Preschool wheezers with persistent symptoms present both during and in between exacerbations (multiple trigger wheeze), and have a distinct airway inflammatory profile compared to those who wheeze only during acute respiratory infections.[46] Preschool confirmed wheezers, with interval wheeze symptoms, have evidence of eosinophilic airway inflammation (Fig. 43.7).[54] Children with this phenotype tend to have a good response to treatments for allergic asthma; in particular they have reduced symptoms and exacerbations if treated with maintenance low-dose inhaled steroids.[97] Although the inflammatory profile is eosinophilic, numbers of mast cells are similar in wheezers and nonwheezers. Little is known about the cytokines driving preschool persistent wheeze, although increased expression of IL-4 in the submucosa has been reported in preschool multiple trigger wheezers.[46] Since leukotriene-receptor antagonists have variable benefit, there are few other therapeutic targets currently available for those with severe preschool wheeze that persists despite high-dose inhaled steroids. It is known that in addition to eosinophilia, features of airway remodeling, specifically increased thickness of the reticular basement membrane, are already present in children with persistent, severe wheeze.[46,54] However, neither of these features is predictive of asthma development by school age. The only pathological abnormality that predicts future asthma is airway smooth muscle,[80] but at present there are no known biomarkers that represent smooth muscle function in preschoolers, so this feature cannot be used to identify future asthmatics. In any event, we lack interventions to prevent the evolution of preschool wheeze to asthma.

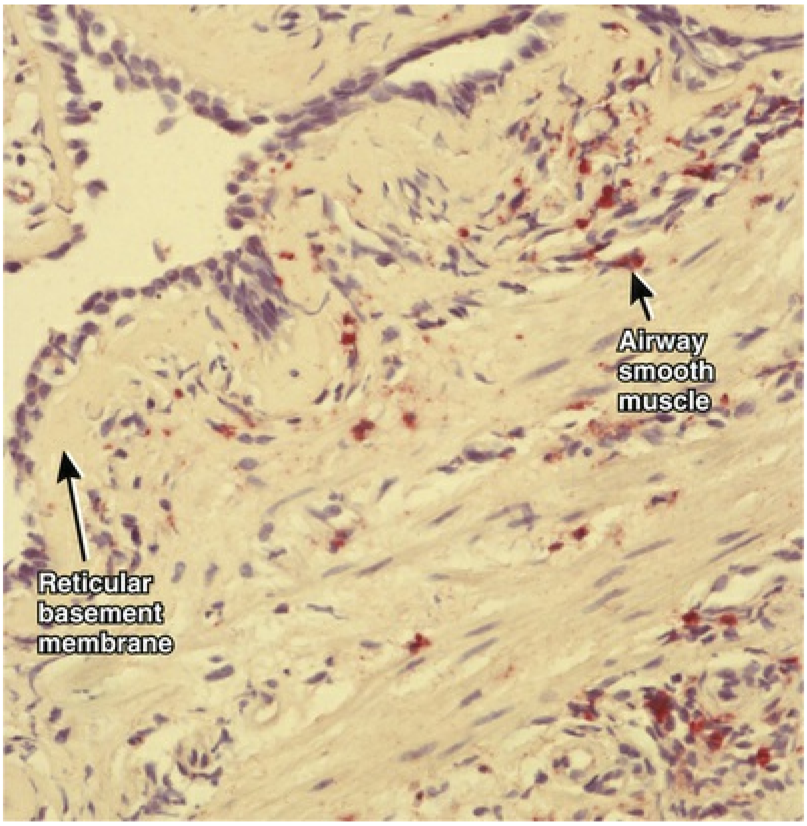

**FIG. 43.7** Endobronchial biopsy from a preschool wheezer showing eosinophilic inflammation and increased thickness of the reticular basement membrane—the hallmark pathological features of asthma in children.

## Impact of Eosinophilic Inflammation on Disease Inception

Evidence for the direct effect of eosinophilic inflammation on clinical disease/symptom manifestation is hard to find in children. Interestingly, murine models of house dust mite induced allergic airway disease have shown the pathophysiological manifestation of disease (airway hyperresponsiveness, total leukocytic inflammation, and airway remodeling) in mice that are deficient in eosinophils is the same as that in wild-type mice,[98] suggesting little role for eosinophils alone in disease inception. In support of this conclusion, clinical trials that have used antiinflammatory therapies targeted to eosinophils (inhaled steroids) to prevent asthma development from preschool wheeze have failed. Inhaled steroids were used in double-blind randomized controlled trials in children with preschool wheeze from several large birth cohorts in the UK,[99] America,[55] and Denmark,[100] but none of these have shown any benefit in terms of secondary prevention. Although preschoolers may benefit symptomatically while taking the treatment, there was no sustained benefit from the inhaled steroids once treatment was stopped.

## Eosinophilic Inflammation and Disease Persistence

In contrast to disease inception, the role of eosinophils in maintaining disease once it has developed is undoubtedly of importance. The mainstay of treatment for asthma, inhaled glucocorticoids, targets eosinophils and they are of huge benefit in established disease. However, glucocorticoids have several mechanisms of action. They reduce airway eosinophils via IL-5, but they also reduce levels of the other Th2 cytokines that drive asthma, so an isolated reduction in eosinophils may not be as effective as the global reduction in allergic Th2 mediators that is achieved by steroid therapy.

Studies in adults have shown that adjusting the dose of maintenance inhaled steroids according to the presence or absence of airway eosinophils (in induced sputum) is significantly better at reducing number of acute exacerbations compared to therapy tailored to clinical disease manifestation (symptoms/lung function).[101] In contrast, directing therapy to sputum eosinophils in school-age children with moderate–severe asthma did not affect exacerbation rate, asthma control, or lung function.[59] In children, no relationship could be demonstrated between airway hyperresponsiveness and FeNO (a noninvasive surrogate marker for airway eosinophilia).[102] In younger preschool children with persistent wheezing, use of inhaled steroids results in an improvement in symptoms and exacerbations,[97] but impact on lung function is less certain. Currently there is significantly more evidence for therapy targeted to airway eosinophilic inflammation in adult patients than there is in children,[103] with the overall documented benefit of reducing eosinophilic inflammation being a reduction in acute exacerbations but not daily asthma control.[104]

## Impact of Immune Maturation and the Developing Airway Microbiome on Preschool Wheeze—Mechanistic Studies

The importance of the changing immune environment in influencing the development of disease in early life is being increasingly recognized. Since mechanistic studies are very difficult in children because of the very limited airway samples that can be obtained, experimental studies that use age appropriate models are being undertaken increasingly to understand the pathogenesis of preschool wheeze and early-onset asthma. A neonatal murine model using intermittent inhaled allergen exposure, with one of the commonest perennial aero-allergens to which children are sensitized, house dust mite (HDM), has been developed. Pups from day 3 of life are exposed to inhaled HDM and assessments of lung function, inflammation, and remodeling made weekly. This model closely mimics the findings in preschool children with multiple trigger wheeze, since there is evidence of airway hyperresponsiveness, eosinophilia, and remodeling.[52] Importantly, it has shown that all pathological and physiological abnormalities develop in parallel in early life, and questions the hypothesis that repeated cycles of inflammation result in structural airway changes. More recently, use of this model has shown that there is a critical time window in early life during which allergen exposure results in exaggerated eosinophilia and AHR. If pups are exposed to allergen in the first week, the degree of airway inflammation and AHR is significantly higher than if allergen exposure starts in adult mice (aged 6–8 weeks). Importantly, the underlying mechanism for this is the relative lack of T regulatory cells in the first 2 weeks of life, which are present subsequently and protect from severe inflammation and AHR. The development of the T regulatory cells is determined by the relatively immature airway microbiome in the first 2 weeks, which develops and becomes increasingly diverse with maturity. The more diverse microbiome results in an appropriate immune environment for the protective T regulatory cells.[105] Other studies in neonatal mice have shown that the first two weeks of life are a critical window of immune maturation, an essential period that determines the type of immune response that develops to either infection or allergen. Infection of neonatal mice with respiratory syncytial virus (RSV) results in a significant increase in T helper 2 cytokine production with compromised function of T regulatory cells.[106] This has highlighted a mechanism by which viral infection targets a host-protective mechanism in early life and increases susceptibility to allergic disease. It is becoming increasingly apparent that environmental exposures during a critical window of immune maturation in early life contribute to susceptibility to long term allergic disease.[107,108] Although the first 3 years seem the likely period of susceptibility in children, we are still unable to identify an intervention that can be used to alter susceptibility and provide protection from the development of allergic responses.

## Gene–Environment Interactions: the Developing Microbiome and Protection From Preschool Wheeze

Wheezing and asthma occur because of the interplay of genetic susceptibility and environmental influences on the developing lungs and immune maturation. Therefore identification of environmental risk factors is as important as deciphering genetic susceptibility in determining mechanisms of disease onset and to find therapeutic interventions. The most striking data showing an environmental effect on asthma outcome is from studies that have very convincingly and repeatedly shown that growing up on a farm has a protective effect on asthma development.[109,110] Specifically, the microbial and endotoxin components of the inhaled products from farmyards are thought to impact the mucosal epithelial innate immune system to skew away from asthma and type 2 immunity and towards a T regulatory cell phenotype.[111] The specific farm environmental effect has recently been shown in a comparison of two populations with similar genetic ancestry, but different farming practices. The Amish practice traditional farming, while the Hutterites practice Westernized industrialized farming. Despite similar lifestyles, the prevalence of asthma was approximately sixfold lower in Amish children compared to the Hutterites.[112] There was a significantly higher endotoxin load in the dust samples from Amish homes and the proportion, phenotype, and function of innate immune cells were significantly different between the two, whereby the Amish had a more robust innate immune response. This study has shown the importance of a specific environmental factor that can influence the onset of wheeze; however, to translate to the clinic, the specific underlying mechanisms need to be investigated. But, this work does demonstrate the importance of the components of inhaled dust and the likely impact they have on shaping the airway microbial profile and immune maturation. The interactions between genetic susceptibility, immune responses, and the airway microbiome are central to understanding the factors that determine the onset of preschool wheeze and how we may prevent progression to asthma.

## Gaps in Knowledge and Thoughts for the Future

Preschool children make up the majority of acute admissions for wheezing in children,[113] and we know that they respond poorly to systemic steroids during exacerbations, and there are few effective maintenance therapies available; but we still have very little knowledge of the mechanisms mediating wheezing in preschoolers. We cannot extrapolate from adult studies,[114] nor from studies in older children with allergic asthma as these are very different diseases. An important focus for future research is therefore to understand the inflammatory and immune pathways that contribute to the development of wheezing in preschool children to allow us to find effective therapies.

Currently, management of preschool wheeze is based predominantly on the clinical phenotype. However, a lack of phenotype stability over time has been acknowledged as a significant factor that limits the effective use of clinical phenotypes alone to manage disease.[115] A limitation of our current approach to managing preschool wheeze is that the underlying presence of airway inflammation or infection is not incorporated in the management plan, only the clinical symptom pattern is used. However, the treatments used, such as inhaled steroids, target eosinophilic inflammation, and could worsen infection by inducing topical immunosuppression. In addition, if eosinophils are not present, then it is unlikely that inhaled steroids will work. Use of objective biomarkers that will identify steroid responders will avoid the inappropriate use of steroids in young children, and importantly will prevent unwanted side effects. It has therefore been suggested that blood eosinophils could be utilized as an attractive biomarker to guide therapy for preschool wheeze.[116] Interestingly, although induced sputum following nebulized hypertonic saline can be obtained safely from preschool children,[117] the relationship between sputum and BAL inflammation is poor in this age group. However, a very close relationship between blood and BAL eosinophils is apparent,[117] confirming blood eosinophils as an important biomarker that needs to be investigated in future studies to determine which preschool wheezers may benefit from inhaled steroids. Interestingly, a recent clinical trial in children aged 1–5 years has shown that the probability of response to daily inhaled steroids was highest in those who had both aero-allergen sensitization and the presence of a blood eosinophilia (defined as >300/μL),[118] suggesting blood eosinophils are a promising biomarker for response to therapy in this age group.

## Severity and Frequency of Acute Wheezing Episodes and Progression to Asthma

A key aspect of preschool wheeze for which we lack knowledge is trying to predict which child will progress to asthma. This is important because we know from cohort studies that those preschoolers who do develop asthma have an early and sustained reduction in lung function.[119] Although several clinical indices have been developed to aid prediction, such as the modified Asthma Predictive Index,[120] most have a good negative predictive value, but few have a positive predictive value much above 50%, making accurate prediction of disease development very difficult. One of the factors to be considered is that an assessment of just the presence or absence of atopy is insufficient. The severity and degree of sensitization is important in predicting wheeze persistence. The subgroup of children with sensitization to multiple allergens and the presence of allergic sensitization at an early age (multiple early atopy) is much more likely to result in disease persistence and progression to asthma.[121]

Until recently, it was thought that symptom pattern might be useful for prognosis, whereby episodic wheeze was much less likely to progress to asthma than multiple trigger wheeze. However, it is now apparent that children with acute attacks of wheeze, especially when severe and frequent, are likely to progress to asthma, regardless of whether they wheeze in between the episodes.[115] Therefore the long-held belief that “viral” wheeze, or transient wheeze is benign and short lived is increasingly challenged. This reinforces the urgent need to investigate the mechanisms mediating wheezing in preschool children so that objective biomarkers other than clinical wheeze pattern or symptoms can be used to more accurately determine acute management and disease progression.

# Specific Clinical Scenarios for Consideration

## Immunology of Asthma Exacerbations

Acute exacerbations are an important feature of pediatric asthma. The most common precipitant of exacerbations, even in patients with allergic disease, is respiratory infection, usually caused by viruses, the most common pathogen being rhinovirus.[122] The airway inflammatory profile present during exacerbations is significantly different to that during stable disease. Children with asthma have altered immune responses to virus compared to nonasthmatic controls. There is a defect in production of antiviral interferons[74] accompanied by an exaggerated Th2 response during viral induced asthma exacerbations. The airway inflammatory infiltrate during exacerbations is composed of neutrophils and eosinophils, with a prolonged duration of inflammation being associated with the viral load.[123] The current approach to treatment is based predominantly on targeting airway eosinophils with the use of systemic steroids. In addition, the most significant clinical effect of newer therapies that are directed to eosinophils, including the anti-IL-5 antibody mepolizumab, is on reduction in exacerbations, suggesting that a surge in Th2 inflammation and eosinophilia is responsible for most exacerbations,[124] and that the associated neutrophilic inflammation may be beneficial and necessary to fight the infection. However, most data related to the airway inflammatory profile present during acute exacerbations comes from studies in adults. This is because it is very difficult to obtain lower airway samples from children during exacerbations when bronchoscopy would be unsafe. A possible avenue that could be pursued to try to obtain some information about acute disease would be to undertake bronchoalveolar (or blind) lavage in children with very severe exacerbations requiring intubation and ventilation.

## Severe Theraphy Resistant Asthma: A Unique Pulmonary Immune Environment

The immunopathogenesis of allergic asthma in children with controlled, mild–moderate disease is a Th2 driven eosinophilia, which is treated effectively in most patients with maintenance inhaled steroid therapy. However, there is a small group of children with very severe disease who remain poorly controlled, with frequent exacerbations despite maximal doses of inhaled steroids, and in some cases, despite maintenance systemic steroids. These children, who are known to be adherent to their prescribed therapy, and in whom all modifiable factors that contribute to poor control such as persistent allergen exposure, have been addressed, have severe therapy resistant asthma (STRA).[125] Most pediatric asthma studies that have assessed airway inflammation and pathology have been undertaken in children with STRA, and so a significant amount is known about the airway inflammatory profile of these patients during stable disease. As a group, they have an airway eosinophilia, but no increase in tissue mast cells or airway neutrophils.[11] They also have very significant and marked sensitization to multiple allergens, and those with concomitant food allergy appear have the most severe disease.[126] The most interesting finding about these patients is the relative paucity of the expected Th2 cytokines in the airways. However, it is known from animal models that the Th2 cytokines are steroid sensitive, so they are likely to be driven down in these patients by high-dose steroids.

Their overall pathological profile as a group is therefore one of a steroid resistant eosinophilia and airway remodeling (see Figs. 43.7 and 43.8).[11] However, it must be remembered that even though they are a small group, there remains marked molecular phenotypic heterogeneity between patients.[43,127] The innate immune system may be important in driving and maintaining very severe asthma in children, since they have increased IL-33 positive cells in the airway walls, which has been shown to be relatively steroid resistant.[36] Moreover, children with STRA have increased airway ILC2 cells, and a subgroup with the most severe allergies, including sensitization to fungal allergens, have the highest levels of IL-33. Although significant steps have been made towards determining some of the mechanisms underlying STRA in children, and it is apparent that this has a different immunopathogenesis to severe asthma in adults, we still have no clinical trials that are targeted to the molecular pathways that drive the disease in children. At present, and disappointingly, novel molecular targets that are being tested are targeted against the Th2 cytokines IL-5 and IL-13, extrapolated from studies in adults.[128,129] However, recruitment of children to these trials is proving difficult because most children can achieve good control if they take their maintenance inhaled steroid treatment regularly. It will not be surprising if efficacy is disappointing, since the molecular phenotype of children is one of eosinophilia with infrequent detection of Th2 cytokines. A feature lacking from our current data relating to the immunology of STRA in children is adequate transcriptomic profiling of airway samples to determine molecular targets and signatures that will allow phenotyping of these patients and achieve personalized treatment.[130] However, unbiased cluster analyses of children with severe asthma have been undertaken and have shown that the overwhelming finding is that children with severe asthma are an extremely heterogeneous group. It is therefore difficult to find a common pathophysiological mechanism that explains disease in all patients, but the identification of subphenotypes is the only way that targeted therapies are likely to be effective.[131] A factor that determines severity and is common to both adult and pediatric patients is that early age of onset and allergen sensitization predict increased severity. A specific feature that defines relative steroid resistance and more severe allergic disease is the presence of fungal sensitization. Severe asthma with fungal sensitization (SAFS) is a recognized subphenotype of severe asthma in both children and adults. However, until recently, the mechanisms mediating this subphenotype were unknown. It is now apparent that SAFS in children is characterized by very high levels of serum Ig-E, worse aero-allergen sensitization, and the need for increased doses of steroids. Use of a neonatal mouse model with inhaled exposure to the fungal allergen *Alternaria alternata* has shown increased levels of the innate cytokine IL-33 compared to HDM exposure, and that the *Alternaria* model is more resistant to steroids than the HDM model. Airway samples from children with SAFS also show higher levels of IL-33 on BAL and biopsy compared to children without SAFS, suggesting this subphenotype is mediated by IL-33 and is more resistant to steroid therapy than severe asthma without fungal sensitization.[132]

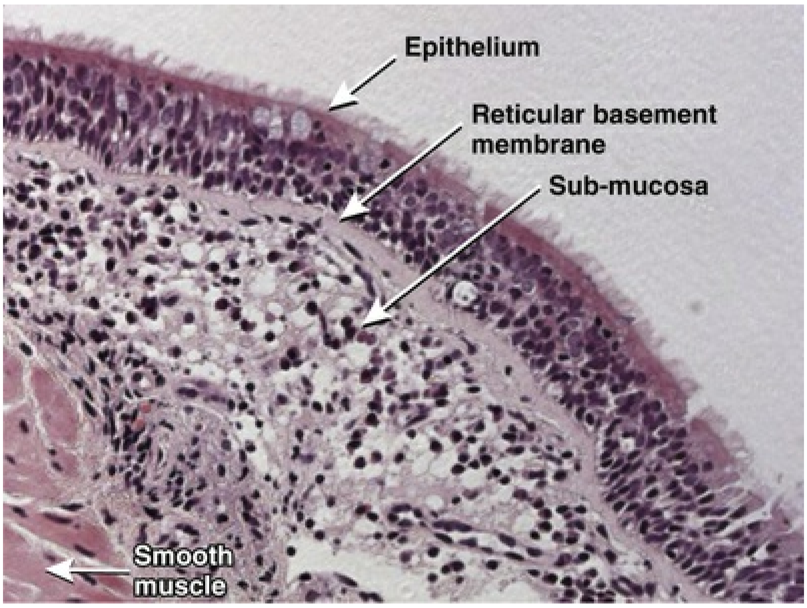

**FIG. 43.8** Endobronchial biopsy stained with hematoxylin and eosin showing the key structural airway features that are altered in childhood asthma.

Another factor that may contribute to the relative steroid resistance seen in children with severe asthma is low levels of serum vitamin D. Children with severe asthma have significantly lower serum vitamin D levels than those with mild–moderate asthma, or nonasthmatic controls.[133] Furthermore, the low vitamin D levels are associated with lower lung function, increased symptoms, and increased frequency of exacerbations.[133] Mechanistically, in a neonatal murine model, vitamin D deficiency has been associated with increased eosinophilia, Th2 cells, and fewer $CD4^+IL\text{-}10^+$ T regulatory cells.[134] Moreover, children with severe asthma have lower BAL levels of the antiinflammatory cytokine IL-10, and reduced capacity for IL-10 secretion from peripheral blood mononuclear cells.[33] However, addition of both steroids and vitamin D results in significantly increased IL-10 secretion and thus improved steroid sensitivity.[33] In addition, ensuring vitamin D sufficiency in severe asthma is important because it has been shown to inhibit IL-33 by enhancing the production of the soluble decoy receptor for IL-33, soluble ST2.[135]

Analyses of severe asthma in adults have repeatedly shown that early (childhood) onset disease is eosinophilic, associated with the most severe atopy, and the worst lung function.[136] Moreover, longitudinal studies that have followed children with asthma to adulthood show that an early loss in lung function is apparent by school age, is greatest in children with severe disease, and is irreversible and tracks to adulthood. Up to 50% of children who had severe asthma at school age had evidence of persistent airflow limitation and COPD by adulthood.[131] These data confirm the life-long impact of severe asthma on adult lung health and highlight the urgent need for future studies to focus on specific mechanisms that mediate severe pediatric asthma so that appropriate disease modifying interventions can be identified to minimize the long-term morbidity from pediatric severe asthma.

# Summary

Interactions between host factors (genes, immune maturation, lung development) and environmental exposures (tobacco smoke, pollution, infection, allergens) and the timing of these interactions are key in the immunopathogenesis and development of disease manifestation in childhood asthma. Currently, we can achieve asthma control in most children with inhaled steroid therapy, but there are specific subgroups for whom we have little to offer. These include preschool wheezers and children with very severe asthma for whom detailed molecular characterization to identify therapeutic targets is urgently needed. At present, our understanding of the mechanisms mediating childhood asthma is very limited, but if we want to progress from the basics of symptom management (our current status) towards disease modification and cure, we must address the need for more detailed understanding of the molecular pathways driving the disease, in different phenotypes, and in children of different ages.

# Asthma in the Preschool Age Child

*Jonathan Grigg MD, Francine M. Ducharme MD, MSc*

## Epidemiology and Burden

Preschool asthma (i.e., wheeze in children 5 years of age and younger) is a common condition. Indeed, a UK study reported that between 1990 and 1998, there was an increase in the prevalence of parent-reported preschool “wheeze ever” (from 16% to 29%), “current wheeze” (from 12% to 26%), “diagnosis of asthma” (from 11% to 19%), and “admission for wheeze” (from 6% to 10%).[1] This high prevalence of wheeze in preschool children results in a high burden of disease. For example, US National Surveillance of Asthma statistics[2] report the highest average annual asthma physician office visits, hospital outpatient department visits, emergency department visits, and hospitalizations in the preschool period than other age groups (Fig. 44.1)—a pattern also found in other countries.[3]

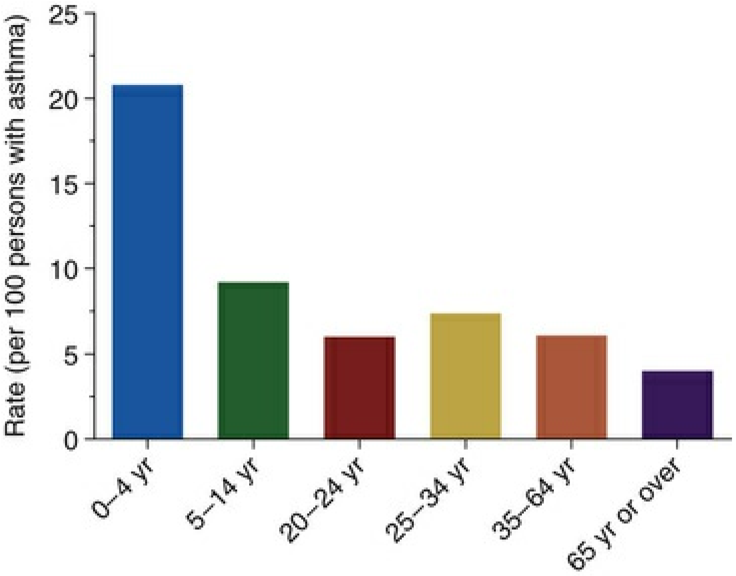

**FIG. 44.1** Emergency department visits for acute wheeze (risk-based) for the United Sates. (Data are the age-specific average annual rates for 2007–2008, from the U.S. National Surveillance of Asthma report [2]).

Episodes of preschool wheeze are frequently associated with signs of an upper respiratory tract infection (URTI).[4] A wide range of infectious agents triggers these episodes (exacerbations). In a prospective cohort study done in Copenhagen, both respiratory viruses (e.g., picornaviruses, respiratory syncytial virus [RSV], and coronavirus) and bacteria (*Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis*) were isolated from the hypopharynx in just over half of preschool wheeze episodes. Bacteria alone were isolated in just over a third of wheeze episodes, and respiratory viruses alone were isolated in 10% of episodes.[5] In preschool children with clinically severe wheeze, human rhinovirus species C (HRVC) is often isolated, especially in those admitted to hospital.[6,7] While an increased virulence of HRVC has been suggested for this association,[8] there is accumulating evidence that gene-environment interaction is important. For some children this may be due to genetic susceptibility.[9] In other children, allergy may be important, potentially because of impaired innate immune response leading to increased viral replication.[10]

## Diagnosis

Asthma is considered an inflammatory disease presenting with episodic or persistent respiratory symptoms associated with variable airflow obstruction to endogenous or exogenous stimuli.[11] However, preschool children with wheeze do not always have airway inflammation between wheezing episodes. As in adults and older children, asthma in preschool is based on recurrent (i.e., two or more) episodes of airflow obstruction and reversibility with appropriate inhaled medication. The diagnosis should be considered in children aged 12 months and older with no suspicion of another condition.[12] Wheeze is the most specific sign of airflow obstruction; it refers to the presence of a continuous musical tone or squeaking commonly heard on auscultation in early expiration or at the end of inspiration. Accompanying signs of obstruction include cough, tachypnea, accessory muscle use, hypoxemia, and, in severe cases, alteration of the mental state. Significant clinical improvement with bronchodilators or corticosteroids is required to document reversibility or, alternatively, fluctuation of symptoms spontaneously over time.

In infants, there is some inconsistency about the diagnostic label applied for wheeze heard on auscultation. A frequent condition in this age group is bronchiolitis—a condition that is associated with signs of a respiratory infection, predominantly, but not exclusively, associated with primary RSV infection of the lower respiratory tract. Infants with bronchiolitis typically do not display significant reversibility, either to bronchodilators or other asthma medications, and in this condition a therapeutic trial is not indicated.[13,14] Although the diagnosis of bronchiolitis is clinical, its varied definition results in diagnostic confusion. In Canada and the United States, a diagnosis of bronchiolitis is a first episode of wheezing in children up to the age of 1 and 2 years, with lower respiratory signs that include wheeze. By contrast, in the United Kingdom and South Africa, the diagnosis of bronchiolitis is mainly limited to infants under 6 months of age, typically with fine crackles but without wheezing.[15] Consequently, wheeze in children, particularly those between 6 months and 2 years, with a first or second episode of respiratory difficulty, and no observed clinical response to asthma medication falls into a clinically unclear area, and is thus frequently labeled as “preschool wheeze” while awaiting a firm diagnosis.

However, preschool wheeze is not a diagnosis, but only a symptom underlying an, as yet, poorly defined pathological entity. By careful observation including, when indicated, a therapeutic trial—clinicians should aim to make a definitive, if not at least a presumptive, diagnosis to apply appropriate therapy. In this regard, a therapeutic trial of asthma medication (bronchodilators with oral corticosteroids [OCS], in case of a moderate or severe exacerbation) would be indicated in children aged 12 months and older to document reversibility.

The diagnosis of preschool asthma (defined previously) is best made on the observation of a trained health care professional (or alternatively a convincing parental history) of two or more episodes with signs of airflow obstruction and reversibility. A thorough history and examination is essential to make a presumptive or conclusive diagnosis of asthma and to exclude alternative diagnoses that may cause respiratory symptoms in infancy and early childhood. There are two important caveats to parent-reported wheeze: the accuracy of the vocabulary and the lower sensitivity of ears compared with a stethoscope. When taking a history, wheeze should be separated from other respiratory sounds by asking about “a high-pitched whistling or squeaking sound from the chest, not the throat.” Parental reporting of wheeze cannot be regarded as the gold standard. For example, in a large population-based study, 17% of families did not define wheeze as a whistling noise, despite being given a description of wheeze in a questionnaire.[16] Showing parents a video of common respiratory signs and then asking them to identify the closest match help distinguish wheeze from other sounds such as stridor and upper airway rattles.[17] However, direct observation of signs of airflow obstruction and reversibility during an exacerbation by a trained health care professional remains the preferred approach. In a child with a prior documented exacerbation or a convincing history of an exacerbation, who does not present with clinical signs of airflow obstruction, an alternative approach is to document reversibility with a 12-week trial of maintenance inhaled corticosteroids (ICS), with parent-reported change in the frequency and severity of chronic and acute symptoms. This treatment should be discontinued if there is no benefit; many would want to exclude the possibility that the child had in fact recovered spontaneously by having a trial period of stopping treatment.

Parents should be asked about the nature and duration of symptoms, exacerbating factors, family history, and presence of atopy, rhinitis, and smoking in the home or car. History and examination should focus on eliminating the other important diagnoses that may cause respiratory symptoms in infancy and early childhood. Alternative diagnoses include structural abnormalities, gastroesophageal reflux, congenital heart disease, foreign body, chronic aspiration, chronic airway infection, and the consequences of extreme prematurity. Red flags for alternative diagnoses include prominent upper airway symptoms, symptoms from the first day of life, sudden onset of symptoms, chronic moist cough, symptoms worse after meals, and weight loss (Table 44.1).[18] Examination should pay attention to clubbing, wasting, severe tonsillar hypertrophy, severe chest deformity, fixed monophonic or asymmetrical wheeze, and cardiac murmurs. A 2016 review of the diagnostic evaluation of infants with recurrent or persistent wheezing (despite adequate inhaled asthma therapy) by the American Thoracic Society recommends flexible bronchoscopy, pH monitoring, and a swallowing study; however, the evidence to support these recommendations was found to be of low quality (Table 44.2).[19]

## Table 44.1

**Differential Diagnosis of Preschool Wheeze**

| Diagnosis | Clinical Features |
|---|---|
| Aspiration syndromes (e.g., gastroesophageal reflux, H-type fistula) | Vomiting, poor weight gain, coughing during feeding, and abdominal distension with H type fistula |
| Inhaled foreign body | Prior episode of coughing or choking (this may be absent), chronic cough |
| Immune deficiency | Wheeze with infections that are severe, persistent, unusual, or recurrent |
| Cystic fibrosis | Cough in first weeks of life, poor weight gain |
| Primary ciliary dyskinesia | Rhinorrhea in first weeks of life, term respiratory distress, with or without situs invertus |
| Bronchomalacia | Harsh, monophonic expiratory sound |
| Bronchopulmonary dysplasia/chronic lung disease of prematurity | Premature birth, home oxygen |
| Cardiac abnormality | Tachycardia, hepatomegaly, pulmonary crackles |
| Post infectious obliterative | History of previous viral infection (especially |

|  |  |
|---|---|
| bronchiolitis | adenovirus), tachypnea |

## Table 44.2

**American Thoracic Society Recommendations for the Diagnostic Evaluation of Infants With Recurrent of Persistent Wheeze Despite Appropriate Inhaled Treatment**

| Investigation | Recommendation | Quality of Evidence |
|---|---|---|
| Fiberoptic bronchoscopy | Should be done | Very low |
| Bronchoalveolar lavage | Should be done | Very low |
| 24-hour esophageal pH monitoring | Should be done | Very low |
| Gastroesophageal scintigraphy instead of pH monitoring | Not preferred to pH monitoring | Very low |
| Swallowing function study | Should be done | Very low |

Ren CL, Esther CR, Debley JS, et al. Official American Thoracic Society Clinical Practice Guidelines: diagnostic evaluation of infants with recurrent or persistent wheezing. *Am J Respir Crit Care Med.* 2016;194:356-373.

Investigations should be tailored to the medical history, physical examination, and suspected diagnosis. For the majority of wheezy preschool children, no investigations are needed. For the minority of children with clinically very severe wheeze (and no red flags on history and examination), it is reasonable to perform a chest radiograph and assess the possibility of sensitization to outdoor and indoor allergens as contributing factors. Exposure to cigarette smoke should be ascertained for all children,[20] with a firm recommendation for a smoke-free environment.

# Natural History

The first complete picture of the natural history of preschool wheeze originated from the Tucson Children's Respiratory Study.[21] Retrospective analysis of this longitudinal dataset from 1246 newborns assessed at both 3 years and 6 years revealed distinct temporal patterns of wheeze that were associated with different factors. First, there are “transient infant wheezers” (the majority of wheezers in this cohort) who wheezed occasionally during the first 3 years of life and then did not wheeze after the age of 3 years. This pattern was not significantly associated with markers of atopy, such as blood eosinophilia or high levels of serum immunoglobulin E (IgE), but was associated with lower lung function (measured in infants prior to their first episode of wheezing) and maternal smoking during pregnancy. Although many of these preschoolers probably met the definition of preschool asthma (obstruction and reversibility with asthma therapy), this pattern was not significantly associated with parent-reported ongoing asthma symptoms at and beyond 6 years of age, suggesting a transient asthma phenomenon. Second, there were “nonatopic wheezers” who begin wheezing at 3 years, but whose wheeze resolved by 6 years. Third, there are “atopic wheezers,” whose preschool wheeze continued as allergic asthma after 6 years of age. Similar trajectories of preschool wheeze have subsequently been reported in other longitudinal cohorts, albeit with subtle differences. For example, an analysis of longitudinal data from the Leicestershire and Avon Longitudinal Study of Parents and Children (ALSPAC) cohorts found patterns consistent between the two cohorts. Those children with persistent wheeze and chronic cough, associated with atopy, have reduced lung function and a poorer prognosis, whereas those with early-onset nonpersistent wheeze have a more favorable prognosis.[22] To date, however, these important epidemiological studies have not produced a clinically useful method for predicting which preschool children will develop asthma symptoms at school age. Indeed, a systematic review of 12 asthma prediction models, including the asthma predictive index (API), found that although some models were better at predicting ongoing asthma at 6 years, and other models were better at ruling it out, no single model could accurately do both.[23] Thus the prediction of whether preschoolers with asthmalike symptoms will continue to have asthma at 6 years, from contemporaneously obtained information, cannot be achieved with sufficient precision in a large proportion of preschool children with wheeze. One main reason is that most children have symptoms only in preschool years and “outgrow” symptoms before the age of 6 years, although, unfortunately, some still have residual lung function impairment.[24] Another reason is the different prevalence of disease in various settings, such as the general population, a family physician practice, or a specialist clinic. When discussing outcomes with parents, clinicians therefore should make it clear that (1) wheezing is very common in the first few years of life, (2) there is a good chance that wheeze will resolve by school age and only a minority of affected children will become lifelong asthmatics, and (3) there is an increased chance of exhibiting ongoing asthma symptoms at school age if wheeze continues beyond 3 years of age, and particularly if it is associated with allergies, although accurate prediction of outcome is not possible. As the pattern of wheeze changes over time, the subgroup of children who become persistent or recurrent wheezers needs careful follow-up and treatment (or at least a therapeutic trial) to improve symptoms and reduce the frequency and severity of exacerbations. Importantly, as a group, preschoolers with wheezing (confirmed or suspected asthma) are at an increased risk of attenuated lung function growth,[25] and those with more frequent or severe exacerbations appear to be most affected.

## Environmental Factors

Exposure to air pollution is associated with an increased risk of developing preschool wheeze. A longitudinal study of US children found that increased exposure to traffic-derived pollution at birth was associated with both preschool wheeze that subsequently resolved by 7 years (transient) and with wheeze that continued to 7 years (persistent).[26] In this study, exposure to traffic-derived air pollution from birth to 1 year of age and from 1 to 2 years of age were both associated with persistent wheeze.[26] There is emerging evidence that prenatal exposure to chemicals, especially bisphenol A and phthalates, increases risk of preschool asthma. For example, a recent study reported that metabolites of these compounds in the urine of pregnant Spanish women are associated with increased risk of wheeze in their offspring during the first 4 years of life.[27]

## Clinical Patterns of Wheeze

There have been several attempts to classify preschool asthma by pattern of symptoms, with a view to better targeting treatment (e.g., intermittent treatment for episodic symptoms). A classification suggested by a European Respiratory Society Task Force is to divide children into those with multiple-trigger wheeze, defined as episodes of wheeze associated with one or more triggers (including but not limited to URTIs and interval symptoms), versus those with episodic wheeze, defined as discrete episodes of wheeze (usually triggered solely by URTI) but without interval symptoms.[28] In cross-sectional surveys, episodic wheeze predominates in children younger than 3 years old.[1,29,30] Whether wheeze patterns are clinically useful remains unclear, as these are unstable over time in the same child, and there is a high variation in the categorization of patterns between pediatricians.[29,31]

# Pathology

Increased bronchial airway smooth muscle (ASM), subepithelial eosinophilia, and increased reticular basement membrane thickening (a pattern found in adult atopic asthma) are reported in a highly selected group of preschool children with severe recurrent wheeze.[32] Furthermore, increased ASM, but not the latter two features, was associated with an increased risk of having ongoing asthma at school age.[33] There are no reported data from bronchial biopsies in children with less severe disease. However, transient increases in urinary cysteinyl leukotriene metabolites and urinary eosinophil activation markers are reported during acute wheeze[34,35]—whether these indirect markers reflect airway inflammation is unclear.

# Treatment

Compatible with the management objectives for older children and adults, the goals of children presenting with preschool asthma are to achieve good control of symptoms, maintain normal activity levels, and minimize future risk—that is, the prevention of future exacerbations, impaired lung growth and function, and side effects.[36] A diagnosis, at least a presumptive one, is essential to achieve this goal, as treatment varies according to the condition. In reviewing the treatment of preschool asthma, this chapter focuses on children who wheeze after 1 year of age and those younger than 1 year with recurrent wheeze. Treatment recommendations do not apply to infants less than 1 year presenting with a first episode of wheezing where bronchiolitis is suspected. The management of preschool wheeze and asthma includes both nonpharmacological and pharmacologic approaches.

## Treatment—Nonpharmacological

All preschool children with suspected or confirmed asthma should have preschool asthma education, with an explanation of the condition, the role of relief and controller medication, and adequate inhalation technique.[11] They should be provided with a self-management plan with written instructions on how to achieve and maintain asthma control ("green zone"), how to manage deterioration ("yellow zone"), and when to consult the physician in case of an asthma attack ("red zone"). While shown effective in all age groups,[37] the only randomized trial that tested an educational guided self-management approach exclusively in preschoolers did not show a significant difference from usual care.[38] However, the authors recognized substantial contamination between groups, with close to half of control patients recalling that they received the same verbal instructions as those in the intervention; further, they acknowledged the absence of documented effectiveness of their recommended intervention—namely preemptive home administration of oral steroids in viral-induced wheezing. Given these study limitations, asthma self-management education remains indicated in preschoolers.[11]

Avoidance of exposure to cigarette smoke and other irritants, and if sensitized, to aeroallergens, should be recommended. Although respiratory illnesses are the most frequent triggers, there is currently no proven, effective approach to avoid the common cold, other than reduced exposure to infected individuals. This is a difficult task when children are placed in childcare during the first years of life or in the presence of numerous siblings.

## Treatment—Pharmacological

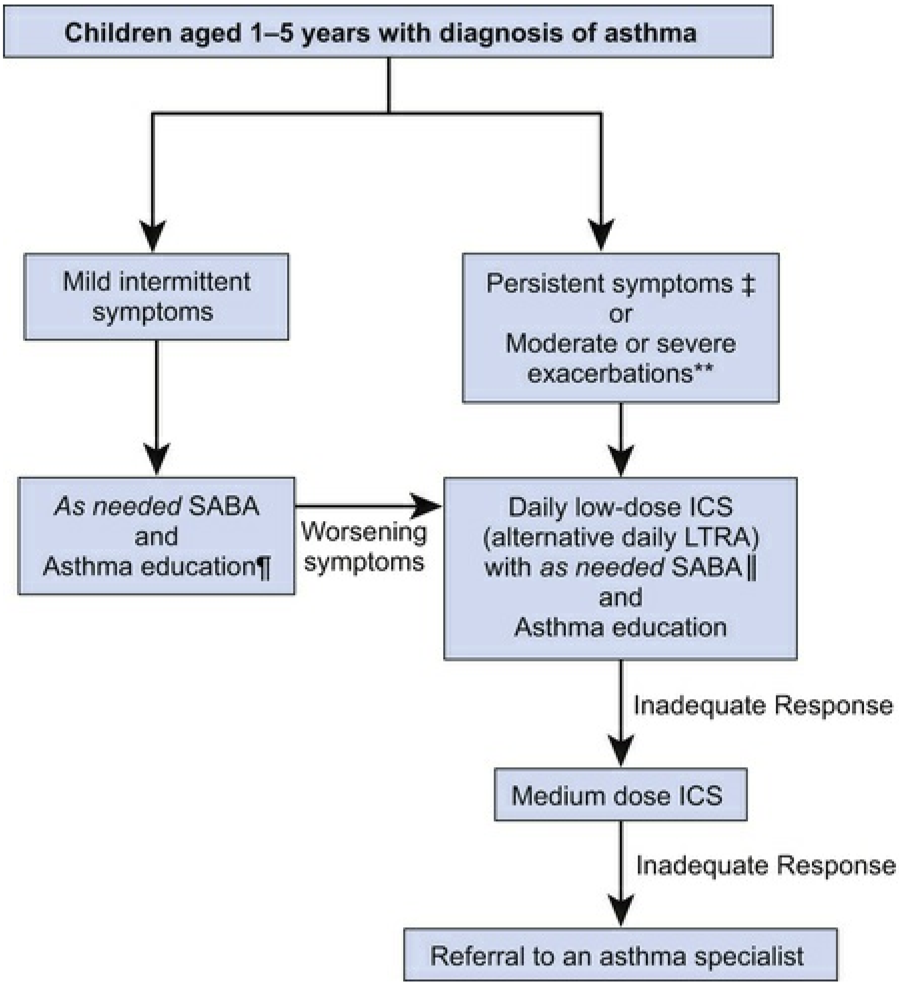
### Challenge to Personalizing Therapy

Despite the worldwide move toward personalized medicine, most, if not all, preschool trials have failed to show convincing evidence that a particular approach is more beneficial for some children than others. Specifically, there is little evidence that children with positive and negative asthma predictive scores respond differently to therapeutic approaches.[39,40] This is probably due in part to poor stability of these phenotypes within the same child over time and high between-physician variability.[29,31] Clearly, significant progress in personalized medicine hinges on the future identification of accurate, precise, and reproducible determinants of response, such as preschool lung function, inflammatory markers, genotype, metabolomics, and other "omics" obtainable in preschool children. Stratification on these determinants must then be proven to be associated with differential treatment response, in randomized clinical trials.

Until then, the therapy shown most effective for the majority of preschoolers with asthma in a rigorously designed trial should dictate the best management. The therapeutic section of this chapter is informed by a literature search that identified systematic reviews of randomized controlled trials and randomized controlled trials of children aged 1–5 years described as having preschool wheeze and/or asthma; trials related to wheeze arising from alternative diagnoses (as discussed previously) were specifically excluded whenever feasible. The pharmacological approach is presented by sections corresponding to the "green zone" (maintaining control) and "yellow zone" (managing deterioration) of a self-management plan and for the initial management of an exacerbation in the acute care setting.

## Preventive Management—"Green Zone"

The evidence supporting therapy in preschool children is derived from randomized controlled trials and systematic reviews of trials, which included children with either asthma or preschool wheezing with specific or a variety of wheezing phenotypes (Fig. 44.2).



Children aged 1–5 years with diagnosis of asthma
Mild intermittent symptoms
Persistent symptoms ‡ or Moderate or severe exacerbations**
As needed SABA and Asthma education¶
Worsening symptoms
Daily low-dose ICS (alternative daily LTRA) with as needed SABA‖ and Asthma education
Inadequate Response
Medium dose ICS
Inadequate Response

Diagnosis and management of asthma in preschoolers: a Canadian Thoracic Society and Canadian Paediatric Society position paper. *Can Respir J Vol*. 2015;22:135-143 and reproduced with permission).

## Daily Preventive Monotherapy

All identified trials pertained to the use of ICS or montelukast, as the leukotriene receptor antagonist (LTRA). With regard to first-line monotherapy, clearly the strongest evidence relates to the use of daily ICS. In a meta-analysis of children with preschool wheeze and asthma by Castro-Rodriguez and Rodrigo,[41] daily ICS was associated with a 41% reduction in the risk of exacerbations of all severity (RR 0.59, 95% CI 0.52–0.67), risk of withdrawals due to exacerbations (RR 0.52, 95% CI 0.43–0.63), symptoms (standardized mean difference [SMD] 0.93, 95% CI 0.49–1.37), and β2-agonist use (SMD 0.63, 95% CI 0.30–0.63), and with a significant improvement in forced expiratory volume in one second ($FEV_1$) (weighted mean difference [WMD] 0.06L, 95% CI 0.05–0.09). A second meta-analysis of trials not included in the Castro-Rodriguez and Rodrigo review (noted previously) done by Ducharme et al[42] pertained to a mixed population of preschoolers with or without atopy (or a positive API); again, daily ICS was found to reduce the risk of moderate exacerbations (i.e., exacerbations needing rescue OCS) by more than 40%, compared with placebo (RR 0.57, 95% CI 0.40–0.80) and was associated with a significantly greater percentage of asthma-free days (mean difference [MD] 5.52 days, 95% CI 2.22–8.81). However, daily ICS therapy is not curative and must be sustained to maintain benefit. For example, during the 1-year period after the cessation of ICS in the Prevention of Early Asthma in Kids (PEAK) trial, there was a similar frequency of symptoms in ICS- and placebo-treated children.[43]

Only two pediatric trials have compared daily LTRAs to placebo in preschoolers. While daily montelukast was associated with a reduction in the number of overall exacerbations in one trial,[44] it was not associated with a reduction in exacerbations requiring rescue oral steroids,[44] or in asthma-free days.[44,45] When data were reanalyzed after including only children with an apparent episodic (viral-triggered) wheeze or episodic asthma phenotype, no statistically significant group reduction in the number of episodes requiring rescue OCS was associated with daily montelukast versus placebo (OR 1.20, 95% CI; 0.70–2.06).[46]

## What Is the Best Preventive Strategy for Specific Wheezy Children?

In the absence of head-to-head trials comparing daily ICS to daily montelukast, the best strategy may only be gauged at present by the size of the effect of each monotherapy compared with placebo. Children showed a greater magnitude of response with ICS than with montelukast. Compared with placebo, potential markers of the best ICS responders were explored. A subgroup analysis of the systematic review by Castro-Rodriguez and Rodrigo[41] suggested a stronger effect for reducing exacerbations in children with a clinical diagnosis of asthma than in those with wheezing (RR 0.50 vs. 0.65, $P = .04$), with no apparent effect of other patient characteristics such as age, atopy, or treatment characteristics such as specific ICS, delivery mode, or duration of therapy. In contrast, in a post hoc analysis of the PEAK trial, preschoolers with a health care utilization in the preceding year, those with aeroallergen sensitization, boys, and Caucasians were better responders to ICS compared with placebo.[47] These apparent conflicting determinants attest to the need for replication.

In the future, the identification of consistent and strong determinants of response is needed to better identify responders, with a confirmatory trial of different therapies, stratified on the presence/absence of determinants (as noted previously) to validate their discriminative ability, will be required. Until then, given the strength of the evidence supporting ICS as opposed to LTRA over placebo, the preferred daily monotherapy should be ICS.

## Adjunct Therapy

To date, there are no published trials exploring adjunct therapy to ICS in this age group.[48]

In summary, the best daily management for preschoolers with repeated wheezing episodes or persistent symptoms is daily low-dose ICS, although it appears slightly more effective in those with a clinical diagnosis of asthma than yet undiagnosed children (i.e., preschool wheezers). The evidence for montelukast is less compelling, partly because of the paucity of trials and apparent lesser efficacy. In view of the difficulty in the recognition of specific phenotypes, initiation of therapy with daily ICS in any child with clinically significant symptoms is reasonable.

## Preemptive Therapy—Yellow Zone

For children with apparent episodic asthma, another approach is the preemptive initiation of an asthma controller when exposed to a known trigger or at the onset of an exacerbation (i.e., intermittent therapy). Preemptive management refers to the initiation of therapy by parents at the onset of an exacerbation. Short-acting β2-agonists are effective in children aged 1 year and over, and should be the first-line relief medication in the yellow zone of the self-management plan.[49] Preemptive administration of ICS, LTRA, and OCS has been formally tested in the context of randomized controlled trials and summarized in systematic reviews.[42,48]

## Preemptive Inhaled Corticosteroids

Six trials, identified by systematic review, compared preemptive ICS to placebo in children less than 6 years. With the exception of one trial in infants and toddlers using 400 µg/day of nebulized budesonide,[50] all trials used a high-dose ICS over 5–10 days (i.e., 1500 µg/day or greater of budesonide or beclomethasone in hydrofluoroalkane [HFA] equivalent).[42] Preemptive low-moderate ICS dose was not effective in preschoolers with mild episodic viral wheeze/asthma.[50] In children with moderate-to-severe viral induced episodic asthma, preemptive high-dose ICS significantly reduced the risk of exacerbations requiring rescue OCS by more than 30% (RR 0.68 [95% CI; 0.53–0.86]; Fig. 44.3A), but was not associated with a significant group difference in the proportion of asthma-free days.[42] Although children with moderate to severe URTI/viral-induced asthma respond to preemptive high-dose ICS, this approach has not been tested in head-to-head comparisons with other groups of children, including those with mild viral-induced asthma and those with persistent asthma, so a clear phenotype-specific response remains to be confirmed.

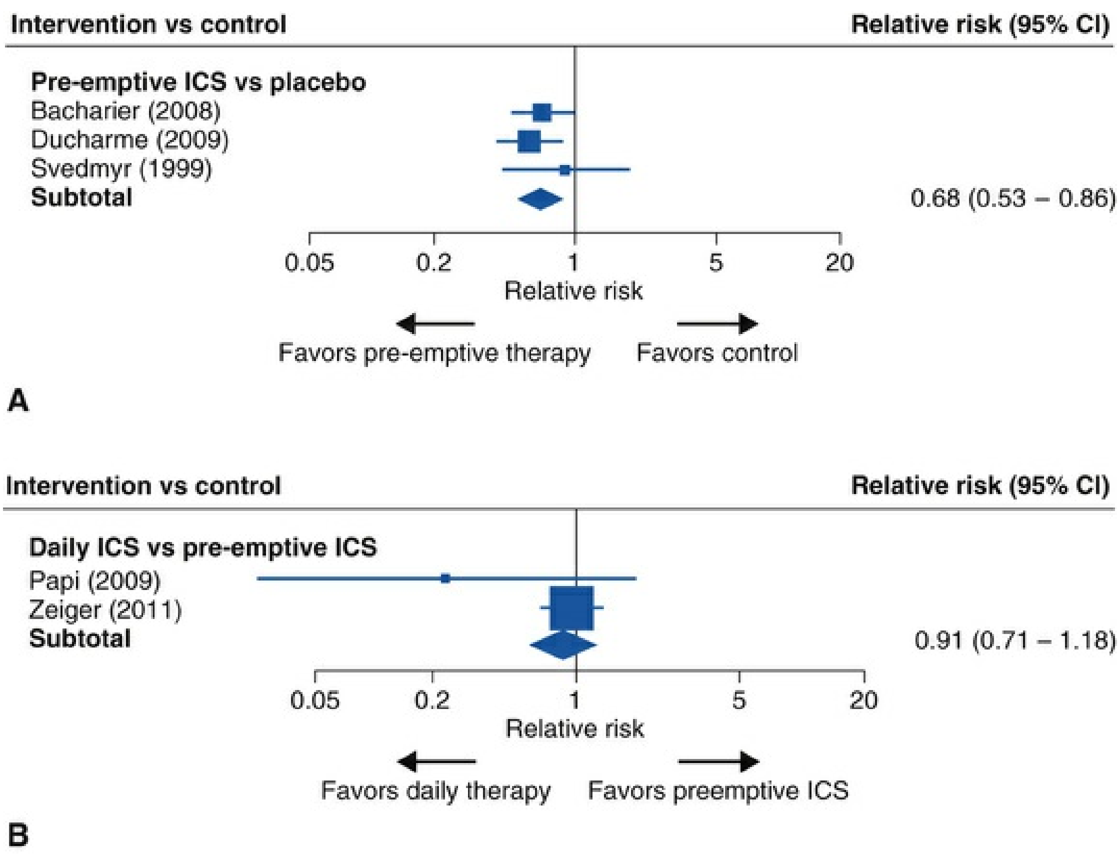

**FIG. 44.3** (A) Comparison of preemptive inhaled corticosteroids (ICS) with preemptive placebo. In preschool children with moderate-to-severe viral induced episodic asthma, preemptive high-dose ICS reduced the risk of exacerbations requiring rescue oral corticosteroids. In these studies, prescription of oral steroids is used as a marker for clinically severe wheeze. (B) Comparison of daily ICS with preemptive high-dose ICS. Results are described as pooled relative risk of preschool children with wheeze or asthma experiencing exacerbations treated with rescue oral corticosteroids. The wide confidence interval underlines the lack of power to draw firm conclusions about the relative efficacy of daily low-dose ICS versus preemptive high-dose ICS. (Figure adapted from Ducharme FM, Tse SM, Chauhan B. Diagnosis, management, and prognosis of preschool wheeze. *Lancet*. 2014;383:1593-1604 and reproduced with permission).

## Preemptive Leukotriene Receptor Antagonists

In three placebo-controlled trials,[40,45,51] the effect of preemptive montelukast (4 mg) was not significantly different from that of placebo for preventing exacerbations requiring rescue OCS (OR 0.77, 95% CI; 0.48–1.25), or reducing asthma-free days.[42] When limited to a subgroup of children with only viral-induced wheezing derived from a single study,[52] there was no significant effect on exacerbations requiring rescue oral steroids, although a small but statistically significant reduction was observed in unscheduled medical attendances due to wheeze (RR 0.83, 95% CI; 0.71–0.98).[46] With only one 3-arm placebo-controlled trial[40] comparing preemptive LTRA to preemptive high-dose ICS in preschoolers with moderate-to-severe intermittent wheezing, neither was associated with less rescue OCS or more episode-free days.

## Preemptive Oral Corticosteroids

OCS initiated by parents at the onset of URTI symptoms, or after not responding to a first dose of bronchodilator, were tested in two trials of children aged 1–5 years with recurrent viral-induced wheeze.[53,54] There was no statistically significant group difference with regard to symptoms, emergency department visits, or hospital admission. The absence of a benefit of preemptive OCS on symptoms during episodes was subsequently confirmed by a post hoc analysis of two randomized controlled trials testing other preemptive strategies.[55]

## Step-Up of Daily Therapy Dose at the Onset of an Exacerbation

There are no identified trials with preschoolers on daily ICS exploring the strategy of increasing the ICS dose at the onset of an exacerbation compared with maintaining the usual dose. Since no beneficial effect was observed in school-aged children and adults,[56] this strategy does not appear promising.

## Which Preemptive Strategy Is Most Effective?

There are no published trials comparing the use of preemptive OCS with either of the two other strategies. Only one trial compared preemptive nebulized budesonide to preemptive montelukast or placebo: there was no statistically significant group difference, despite a nonsignificant trend favoring ICS over LTRA for rescue oral steroids and symptom-free days.[40] Consequently, there is insufficient evidence to firmly conclude on the equivalence or superiority of any of these three preemptive options.[42] However, in view of the absence of a significant effect of preemptive LTRA or OCS on episode-free days, rescue OCS, health care utilization, or symptom severity compared with placebo, the strength of the evidence clearly supporting preemptive high-dose ICS over placebo for reducing exacerbations requiring rescue OCS would support this latter strategy over the former two in preschoolers with episodic moderate to severe viral induced asthma.

## Daily Versus Preemptive Asthma Controller: What Is the Best and Safest Approach?

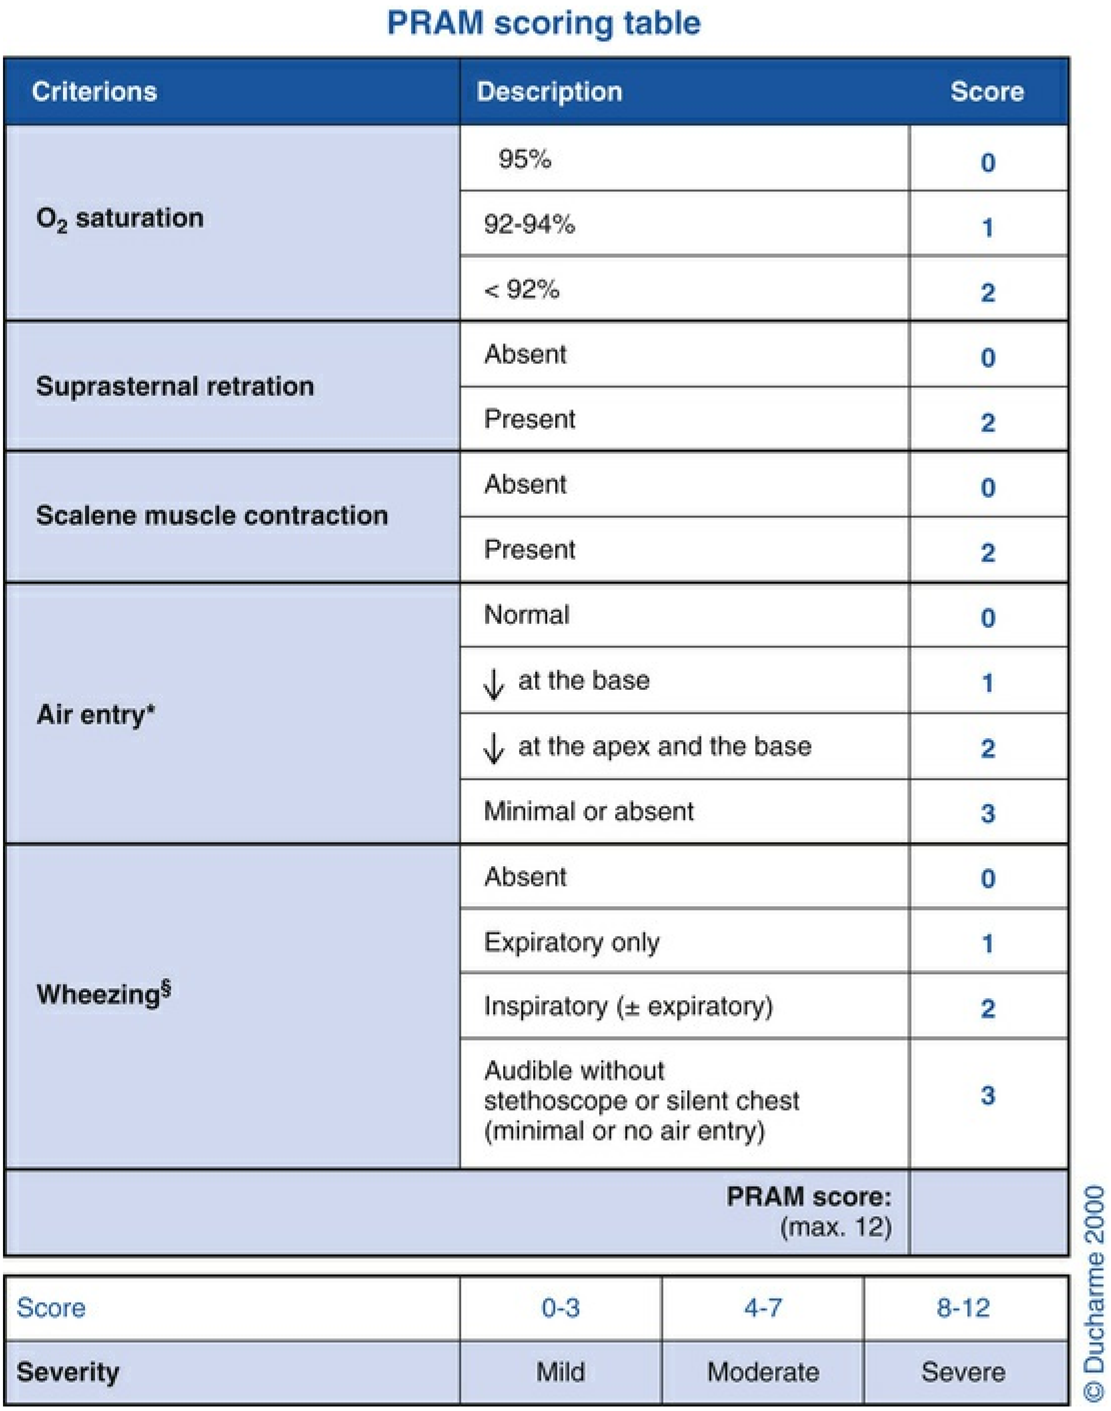
With regard to efficacy, two trials of preschool children with recurrent moderate to severe episodic viral-induced wheeze or asthma, with and without a positive API, compared daily low-dose ICS with preemptive high-dose ICS: there was no statistically significant group difference with regard to the need for rescue OCS (0.91 [0.71–1.18]).[42] In these two trials, initiation of OCS therapy was used as a marker for clinically severe wheeze. The wide confidence interval (see Fig. 44.3B) underlines the lack of power to draw firm conclusions about the relative efficacy of daily low doses versus preemptive high-doses of ICS.[42] However, daily ICS trials included a variety of children with interim symptoms, atopy, or recurrent viral-induced asthma, such that this approach appears as the most effective first-line therapy irrespective of apparent phenotype and is recommended as such by most national and international guidelines.[12,36,57,58] By contrast, preemptive high-dose ICS was tested in younger preschool children with moderate or severe viral-induced wheezing with no or minimal interim symptoms, such that this approach may be best reserved to those with two or more exacerbations requiring an emergency department visit or rescue OCS, who failed to respond to daily ICS.[12] Because of the risk of ICS overuse by parents and physicians, the preemptive high-dose ICS strategy should be reserved for preschool children who remain poorly controlled, despite good compliance with a medium dose of daily ICS, under the supervision by asthma specialists with close monitoring of potential side effects and follow-up of efficacy.

### Safety Profile.

Clinical trials conducted in preschoolers have seldom documented potential adverse effects systematically (specifically growth), and impact on adrenal function has been insufficiently studied. Concerning the former, only two trials were identified in a systematic review of randomized controlled trials. In the subgroup of toddlers or infants ($n = 903$), the change in the baseline of height (cm) during 1 year of ICS (MD −0.58, 95% CI; −0.55 to −0.20, $P = .003$) was of similar magnitude than that observed in prepubertal school-aged children (MD −0.46, 95% CI; −0.75 to −0.16, $P = .004$).[59] In another trial, daily ciclesonide up to 200 μg/day for 24 weeks was not linked with any detectable impairment in growth or adrenal function in children less than 6 years.[60] This systematic review, including mostly prepubertal school-aged children, showed a significant molecule- and dose-dependency in the magnitude of growth suppression associated with ICS.[59] Compared with placebo, repeated intake of preemptive high-dose ICS has been associated with a group difference of 0.6 cm, equivalent to a 4 percentile point difference in growth,[30] analogous to that reported with daily low ICS dose.[43] The potential for overuse of preemptive high-dose ICS by both parents and physicians has led to calls for caution in the use of this strategy. In the absence of solid data for preschool children, the selection of the safest molecules and careful monitoring of growth seems to be the most prudent approach for any child receiving daily or preemptive ICS.

## Treatment—Initial Management of Exacerbations in the Acute Care Setting

As for older children and adults, the initial step is to assess asthma severity and apply severity-specific management. Several signs suggest increasing severity of airflow obstruction, namely accessory muscle use, wheezing, oxygen saturation at or below 92%,[12] decreased air entry, agitation, or apathy.[61] Use of validated standardized clinical scores, such as the 12-point pediatric respiratory assessment measure (PRAM, Fig. 44.4),[62] has been shown to be effective and practical to apply guidelines and reduced hospital admissions.[63,64]



PRAM scoring table

| Criterions | Description | Score |
|---|---|---|
| $O_2$ saturation | 95% | 0 |
| | 92-94% | 1 |
| | < 92% | 2 |
| Suprasternal retration | Absent | 0 |
| | Present | 2 |
| Scalene muscle contraction | Absent | 0 |
| | Present | 2 |
| Air entry* | Normal | 0 |
| | ↓ at the base | 1 |
| | ↓ at the apex and the base | 2 |
| | Minimal or absent | 3 |
| Wheezing§ | Absent | 0 |
| | Expiratory only | 1 |
| | Inspiratory (± expiratory) | 2 |
| | Audible without stethoscope or silent chest (minimal or no air entry) | 3 |
| | PRAM score: (max. 12) | |

| Score | 0-3 | 4-7 | 8-12 |
|---|---|---|---|
| Severity | Mild | Moderate | Severe |

The Preschool Respiratory Assessment Measure (PRAM): A responsive index of acute asthma severity. Pages 762-768, Copyright © 2000, with permission from Elsevier.)

## Bronchodilators

Short-acting β2-agonists are the most effective bronchodilators, with a significant bronchodilator effect documented in children aged 1 year and over.[49] In a meta-analysis of children aged 1–18 years, with moderate or severe airflow obstruction, the addition of ipratropium bromide to β2-agonists has been shown to be superior to β2-agonists alone.[65] The administration of salbutamol by metered dose inhaler with a spacer was more cost-effective and associated with fewer side effects than by nebulizer in young children (1–4 years) with moderate and severe acute asthma.[66] In these patients, repeating the dose of β2-agonists at 20 minutes, the time of peak action, led to better and more sustained bronchodilation.[67] Supplemental oxygen should be provided for children with hypoxemia.

## Oral Corticosteroids

National and international guidelines recommend the addition of OCS in preschoolers with moderate or severe airflow obstruction and in those with poor responses to bronchodilators. This view is consistent with a systematic review of randomized controlled trials, confirming a 25% reduction in hospital admission rate in children treated with systemic corticosteroids compared with placebo in pediatric trials that collectively included about 50% preschoolers[68]; one trial included only preschoolers,[69] whereas the other four pediatric trials included both preschool and school-aged children.[70–73] The efficacy of OCS was challenged by a 2009 placebo-controlled trial in children aged 10 months to 5 years, with viral-induced wheezing showing no apparent effect on the duration of hospital stay; young age and viral infection were suspected explanations for the negative findings.[74] By contrast, a recent cohort study conducted in children aged 1–17 years presenting with a moderate or severe asthma exacerbation and treated with a severity-specific treatment protocol with β2-agonists, ipratropium bromide, and OCS reported a very low treatment failure rate of 17%.[75] After adjusting for baseline severity (i.e., PRAM score and oxygen saturation), the presence of symptoms between exacerbations, viral detection, and fever were significant predictors of failure of emergency management. Of note, age was not significantly associated with treatment response. These data suggest that a higher rate of respiratory infections, rather than age, may explain the apparent higher treatment failure observed in preschoolers presenting with acute asthma.

In summary, the evidence specific to preschoolers to support the efficacy of OCS in those with repeated episodes of airflow obstruction and who meet the criteria for asthma is scarce; consequently, it remains debated whether one should restrict or liberalize its use in preschool children with ongoing wheeze, despite an initial adequate dose of inhaled bronchodilator therapy. By contrast, children who are younger than a year, with a first episode of wheezing, who do not meet the operational definition of asthma (obstruction and reversibility with asthma medication) are unlikely to benefit from OCS, irrespective of severity or setting. In children falling between these two extremes, OCS should be used sparingly and on an individual trial basis only.

## Inhaled Corticosteroids

A systematic review of eight randomized controlled trials of children (and an unspecified proportion of preschoolers) presenting to the emergency department with an acute asthma exacerbation concluded that there was a beneficial effect of ICS alone in reducing the rate of hospital admission. Although there was no significant group difference in hospital admission rate between groups, the power was insufficient to conclude regarding the equivalence between ICS versus OCS for preventing hospital admission, relapse, and the need to rescue OCS. Although promising, the evidence is thus insufficient to recommend replacing oral steroids by high-dose ICS therapy (which is also more costly), either in emergency management, or upon discharge from the emergency department.[76]

### Magnesium Sulfate

Treatment with intravenous magnesium sulfate showed a significant benefit in children and adults with acute severe asthma, but not in those with milder severity.[77] Several pediatric trials are ongoing and will help confirm the best route (nebulized vs. intravenous) and indication for magnesium sulfate in children, including preschoolers.

### Antibiotics

The observation that bacterial colonization of the hypopharynx is common during episodes of preschool wheeze (discussed previously) led researchers to assess the efficacy of azithromycin. In a randomized placebo controlled trial that recruited infants from the COPSAC cohort, Stokholm et al[78] found that a course of azithromycin started 3 days into an episode reduced the mean duration of subsequent troublesome lower respiratory symptoms by about 4 days. Since improvement of symptoms with azithromycin may be due to an improvement in (clinically trivial) bronchitic cough, and not wheeze,[79] azithromycin cannot be recommended at this time.

## Future Directions

As most of the airflow obstruction reported by 7 years of age in children with asthma is not attributable to prenatal or perinatal programming, there is a window of opportunity for interventions in the preschool years to prevent early airway remodeling. This may imply finding novel strategies to prevent key triggers such as viral infections, to reduce the frequency and severity of viral-induced exacerbations, and to improve the monitoring of preschool lung function to identify “unrecognized” persistent airway obstruction. Although there are no long-term trials to determine if sustained controller therapy introduced early could prevent lung function impairment in school-aged children with asthma symptoms, it seems prudent to initiate controller therapy early.

Until determinants of a differential response to therapy are identified, the best approach for preschool children with recurrent or chronic wheeze is the administration of daily-ICS at the lowest effective dose. A proven effective alternative for children with moderate and severe viral-induced exacerbations is preemptive high-dose ICS, with safeguards to prevent overuse by parents and physicians. Future advances in objective markers of phenotype would enable major advances in personalized therapy. Trials are needed to clarify the role of adjunct therapy and immunotherapy in this young age group. Meanwhile, careful regular reassessments remain the cornerstone of an appropriate follow-up to ensure an adequate response and enable timely reduction to the minimal effective dose.

# Wheezing in Older Children

## Asthma

*Carolyn M. Kercsmar MS, MD, Karen M. Mcdowell MD*

### Introduction

Wheezing is a musical, high-pitched, largely expiratory sound, typically made through the partially obstructed larger airways, most commonly caused by asthma in school-age children. Nevertheless, wheezing can also be generated by narrowing in the distal trachea and by glottic closure. A number of other conditions can cause both acute and chronic wheezing in children, but many causes are associated with other symptoms that generally distinguish them from asthma (Box 45.1). The major focus of this chapter will be on the diagnosis and treatment of asthma in children beyond the preschool years.

**Box 45.1**

#### Causes of Wheezing in Older Children

$\alpha$1-antiprotease deficiency (adolescent, young adult)
Anatomic lesion or airway compression
Angioedema
Aspiration/gastroesophageal reflux
Asthma
Bronchiectasis
Bronchogenic or pulmonary cyst
Congestive heart failure
Cystic fibrosis
Eosinophilic bronchitis
Exercise-induced asthma
Foreign body aspiration
Granulation tissue in intrathoracic airway
Hypersensitivity pneumonitis
Immotile cilia syndrome
Immune deficiency
Infection
Inflammation of lower airway
Irritant inhalation (smoke, illicit drugs, cocaine)
Lymph nodes (mediastinal, paratracheal)
Mycoplasma
Pertussis
Postinfection
Sarcoidosis
Tumor (carcinoid, lymphoma)
Vascular ring
Vasculitis (Wegener granulomatosis, other)
Virus (adenovirus, respiratory syncytial virus [RSV], human metapneumovirus, parainfluenza, influenza)
Vocal cord adduction/dysfunction

As defined in the National Heart, Lung, and Blood Institute (NHLBI) guidelines, asthma is characterized by variable, reversible obstruction of air flow (but not completely so in some patients), which may improve spontaneously or may subside only after specific therapy.[1] Airway hyperreactivity, defined as the inherent tendency of the trachea and bronchi to narrow in response to a variety of stimuli (e.g., allergens, nonspecific irritants, or infection), is also a prominent feature. Both the airway obstruction and hyperreactivity may be associated with chronic, dysregulated airway inflammation that involves many cell types (e.g., eosinophils, lymphocytes, neutrophils, epithelial cells, airway smooth muscle, fibroblasts) and mediators (e.g., cytokines, chemokines, enzymes, growth factors, IgE). Symptoms of wheeze, cough, and shortness of breath are episodic in most patients but may occur daily in some. Asthma is now viewed as an "umbrella term" for a complex, heterogeneous disorder with numerous phenotypes and endotypes that differ in children and adults. Although all asthma phenotypes demonstrate airway obstruction, the pathophysiological processes, genetics, natural history, and response to treatment differ widely.

Although there has been an increased awareness of the prevalence of childhood asthma, substantial physical, psychological, and socioeconomic morbidity continue to occur. Among the 7 million children younger than 18 years of age in the United States with asthma, it is estimated that each year more than 10 million school days are lost, 3 million sick visits are made to health care providers, and more than 450,000 hospitalizations occur.[2] The annual direct and indirect health care costs for treatment of asthma were recently estimated at over $50 billion per year in the United States. Poor, disadvantaged minority children who reside in central urban areas have both the highest prevalence and greatest morbidity. Nevertheless, both acute health care utilization and mortality rates from asthma appear to have stabilized and for some groups, declined slightly in recent years, following a steady rise in the period from 1980 to the mid-1990s.[2] Mortality remains rare and is declining, and less than 150 children and adolescents younger than 15 years of age in the United States die annually from asthma.

## Pathology

Examination of postmortem lung specimens of patients who died from asthma shows marked hyperinflation with smooth muscle hyperplasia in the bronchial and bronchiolar walls, thick tenacious mucous plugs often completely occluding the airways, markedly thickened basement membrane, and variable degrees of mucosal edema and denudation of bronchial and bronchiolar epithelium (Fig. 45.1).[3] Eosinophilia of the submucosa and secretions is often prominent whether or not allergic (IgE-mediated) mechanisms are present. Airway smooth muscle mass is also increased in the airways by school age and may begin in the preschool years. Mucous plugs contain layers of shed epithelial cells and eosinophils, as well as neutrophils and lymphocytes. Although the exact role of airway eosinophils in causing and perpetuating the asthma phenotype remains controversial, eosinophil products (e.g., major basic protein and other proteases) may play an important role in the destructive changes observed. The mucosal edema with separated columnar cells and stratified nonciliated epithelium, which replaces ciliated epithelium, results in abnormal mucociliary clearance. Mast cells are increased in airway smooth muscle of asthmatics. In addition, there is increased mast cell degranulation, which is often worse in those with more severe asthma. Submucosal gland hypertrophy and increased goblet cell size are not constant features of asthma, but mucous metaplasia caused by increased synthesis and stores frequently occurs across all ranges of asthma severity. The thickened basement membrane caused by submucosal deposition of type IV collagen and various other materials is a striking feature of asthma and has been reported even in mild asthmatics. Basement membrane thickening is thought to occur early in the disease, but its pathologic significance remains to be determined. All of these findings have been observed in symptom-free asthmatic individuals who died accidental deaths, as well as in endobronchial biopsy specimens from research subjects (Fig. 45.2). Significant basement membrane thickening in airway mucosal biopsies taken from pediatric patients with severe asthma has been observed in the absence of active eosinophilic or neutrophilic infiltrates.[4,5] Moreover, normal lung function as measured by forced expiratory volume in 1 second ($FEV_1$) can be achieved by patients with severe airway remodeling. These observations call into question the role of inflammation and remodeling in asthma that is difficult to control. Although an occasional patient may show localized bronchiectasis and small focal areas of alveolar destruction, these are not characteristic of asthma, and there is little evidence that asthma leads to destructive emphysema. However, the incomplete reversibility of air flow limitation seen in some asthmatics suggests that a phenotype exists that may be considered a form of chronic obstructive pulmonary disease (COPD), the so-called overlap syndrome.[6]

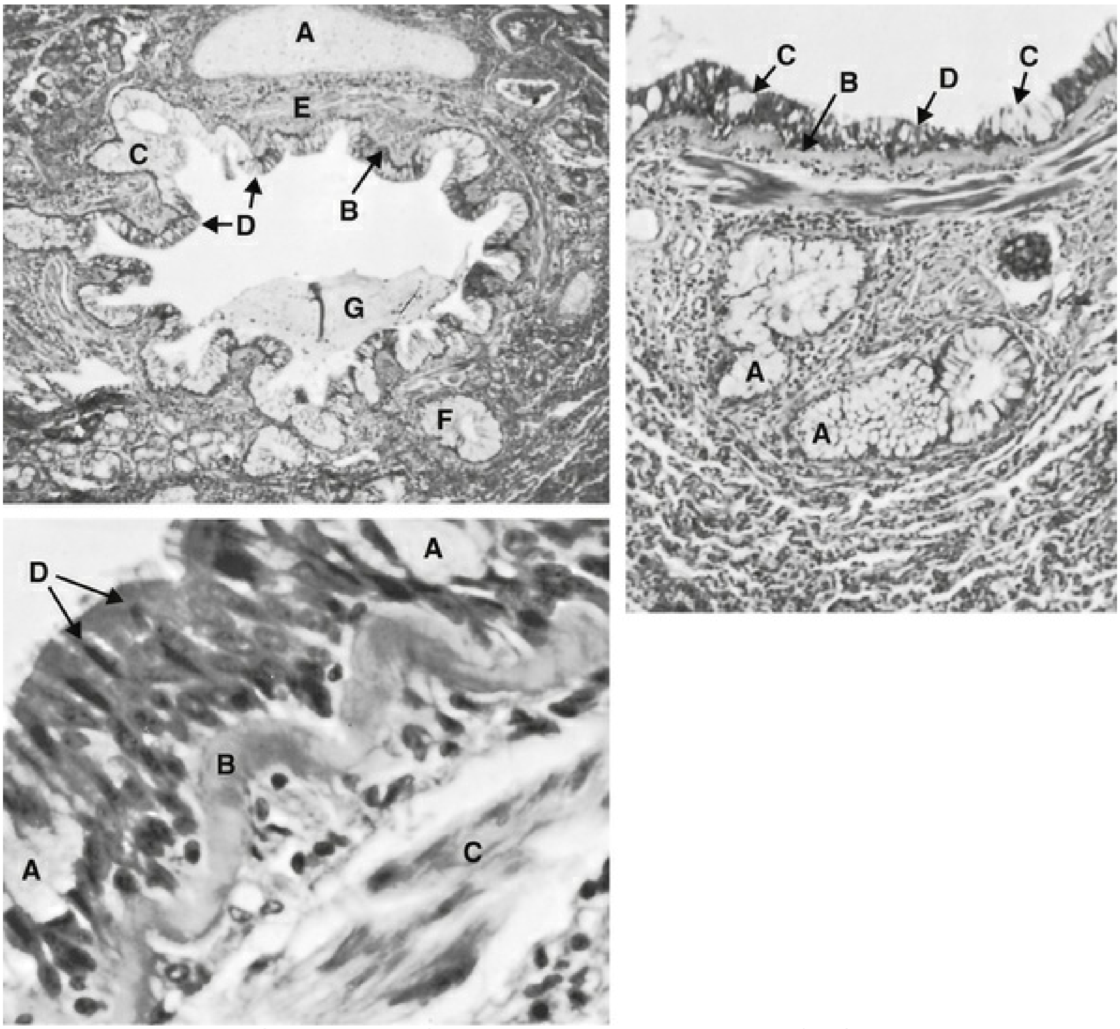

**FIG. 45.1** Sections of asthmatic lung. *Top left,* Cross-section of bronchus (original magnification ×66) showing cartilage *(A),* thickened basement membrane *(B),* epithelium containing many goblet cells *(C),* area of many ciliated epithelial cells *(D),* connective tissue *(E),* mucous gland *(F),* and mucous plug *(G). *(B)*, connective tissue *(C)*, and ciliated respiratory epithelial cells *(D).*

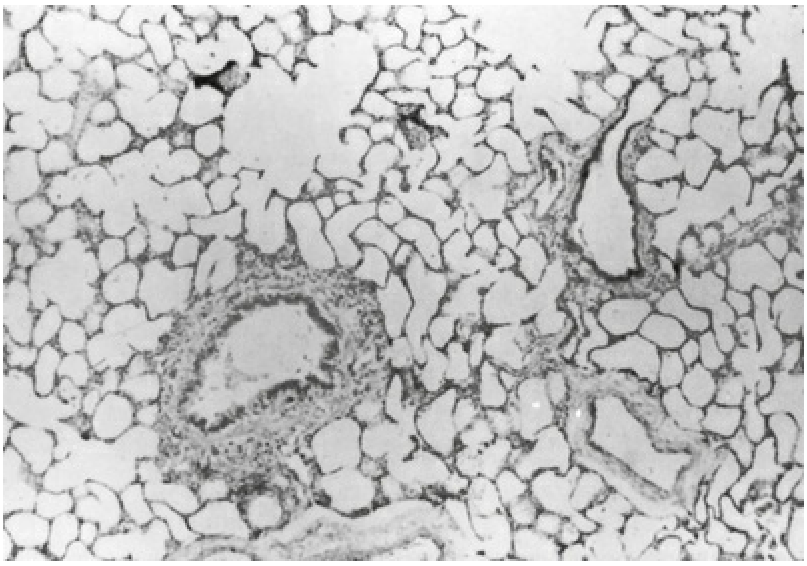

**FIG. 45.2** Autopsy specimen from an asthmatic child who died from toxic ingestion. Note the infiltration of cells around the bronchus with sloughing of epithelial cells into the bronchial lumen. The alveoli all appear normal.

# Pathophysiology

Air flow limitation in asthma results from a combination of obstructive processes, principally mucosal edema, bronchospasm, loss of alveolar tethering points, and mucous plugging. The relative roles of these processes in producing obstruction may differ, however, according to the age of the child, the size and anatomy of various portions of the airway, the type of agent precipitating obstruction, and the duration and severity of asthma. An example of acute bronchoconstriction following bronchial lavage with normal saline in a child with asthma can be viewed in the video clip. Note the furrowing of the bronchial mucosa prior to lavage, which is associated with smooth muscle hypertrophy in the airway (Video 45.1▶).

Airway obstruction results in increased resistance to air flow through the trachea and bronchi and in decreased flow rates due to narrowing and premature closure of the smaller airways. These changes lead to a decreased ability to expel air and result in hyperinflation. Although pulmonary overdistention benefits respiration by helping to maintain airway patency, the work of breathing increases because of the altered pulmonary mechanics. To a certain extent, increasing lung volumes can compensate for pulmonary obstruction, but compensation is limited as tidal volume approaches the volume of pulmonary dead space, with resultant alveolar hypoventilation.

Changes in resistance to air flow are not uniform throughout the tracheobronchial tree, and because of regional differences in this resistance, the distribution of inspired air is uneven, with more air flowing to the less resistant portions. In most patients with asthma, both larger and smaller airways are obstructed, but some patients may have small airway obstruction primarily, or even exclusively.[7] The pulmonary circulation also is affected by hyperinflation, which induces increased intrapleural and intraalveolar pressures and uneven perfusion of the alveoli. The increased intraalveolar pressure, decreased ventilation, and decreased perfusion (the last through hypoxic vasoconstriction) lead to variable and uneven ventilation-perfusion relationships within different lung units. The ultimate result is early reduction in blood oxygenation, even though carbon dioxide is eliminated effectively because of its ready diffusibility across alveolar capillary membranes. Thus, early in acute asthma, hypoxemia occurs in the absence of $CO_2$ retention. The hyperventilation resulting from the hypoxemic drive causes a fall in partial pressure of carbon dioxide in alveolar gas ($Pa_{CO_2}$). However, as the obstruction becomes more severe and the number of alveoli being adequately ventilated and perfused decreases, a point is reached at which $CO_2$ retention occurs.

Alterations in pH homeostasis result from respiratory and metabolic factors. Early in the course of acute asthma, respiratory alkalosis may occur because of hyperventilation. Metabolic acidosis can occur because of the increased work of breathing, increased oxygen consumption, and as a result of excessive β-adrenergic agonist treatment. The metabolic acidosis usually results from lactic acid accumulation, which most commonly occurs as a result of high and frequent doses of β-adrenergic agonist use. In such cases, the acidosis resolves as the β-agonist use is tapered. The mechanism of β-adrenergic agonist induced lactic acid production is somewhat controversial, but most likely results as a consequence of the increased plasma glucose concentration (caused by both beta-agonist and systemic glucocorticoid administration) and its conversion via glycolysis to pyruvate, which is then converted to lactate.[8] When respiratory failure is superimposed, respiratory acidosis may result in a precipitous decrease in pH.

In short attacks of acute asthma, bronchospasm, mucosal edema, or both can occur. In a minority of asthmatics, acute severe episodes are characterized by neutrophilic, not eosinophilic infiltration, and bronchospasm occurs with little mucus secretion. These episodes may have an abrupt onset and cause severe or life-threatening symptoms. Mucous secretions become far more important as a cause of obstruction as the inflammation becomes more intense and prolonged, and when damage to and sloughing of epithelial cells impairs mucociliary function and increases reflex bronchoconstriction.

## Inflammatory Cell Biology and Asthma Etiology and Pathophysiology

Although tremendous strides have been made in the cellular and molecular biology of asthma in the past two decades, a complete understanding of the causative factors and those responsible for perpetuating the asthmatic state remain inadequately explained. Current data support the hypothesis that inflammation underlies the pathophysiology of asthma, and the airway epithelium, inflammatory leukocytes, multiple immune cells, and other airway structural cells all play a role.[9,10] The mechanisms producing airway inflammation are legion, cross-talk among various pathways occurs, and the predominant mechanisms responsible for cellular dysfunction vary among asthma phenotypes. The cell–cell communications that initiate and perpetuate asthma likely result from inhaled stimuli such as inhaled allergens, respiratory viruses, and air pollutants (particulate and gaseous) that cause airway epithelial cells to secrete cytokines, interleukins, and other mediators. In turn, these proinflammatory agents act on resident cells in the subepithelial layer, (e.g., dendritic cells, mast cells, and lymphoid cells, including lineage negative innate lymphoid cells) to recruit other leukocytes and the release of Th2 cytokines such as IL-4, IL-5, and IL-13. Biologically active neuropeptides and acetylcholine can also be released from afferent nerves in the epithelium by similar environmental triggers/irritants. The ongoing recruitment of T lymphocytes and release of other mediators, such as IL-17 and IL-33, further enhances the inflammation and dysfunction of the epithelium and airway smooth muscle.

The propensity to develop IgE-mediated sensitization to environmental allergens, particularly in association with rhinovirus infection, coupled with subsequent exposure, is one of the strongest predictors for the development of childhood asthma. The persistence and chronic activation of mast cells, dendritic cells, eosinophils, and lymphocytes in the airways as a result of Th2 cytokine-mediated events (e.g., recruitment of circulating inflammatory cells, interruption of apoptosis) may be important in producing chronic asthma. In addition, innate immune responses modulated by Toll-like receptor recognition and Th17 cells also may be operative in some asthma phenotypes, such as those with more severe disease and neutrophilic predominance in the airways.[11] Impaired production of natural airway defense mediators such as lipoxins, resolvins, and protectins (all important in the active resolution of airway inflammation) may also promote a proinflammatory state in the asthmatic airway. Prolonged or recurrent episodes of inflammation are associated with progressive structural and functional changes in the airway epithelium, musculature, and connective tissue. The continued dysregulation of the cytokine networks perpetuates inflammation in what now may be the structurally altered airways of chronic asthma. Several specific effector mechanisms (e.g., IgE, arachidonic acid metabolites, mast cell proteases, numerous cytokines, thymic stromal lymphopoietin [TSLP], nitric oxide [NO], the β-adrenergic receptor [BAR], growth factors, the airway microbiome, and intrinsic muscular abnormalities) appear to play key roles in airway inflammation and are discussed further in Chapter 7.

## Natural History and Prognosis

Knowledge of the natural history of asthma remains incomplete, but several longitudinal studies have added substantial insight. The widespread notion that most children "outgrow" their asthma in adolescence is only partially true. Between 30% and 70% of children with episodic asthma have less severe or absent symptoms by late adolescence, and some features of childhood presentation and course seem to predict clinical outcome. The presence of allergic sensitization, female sex, and severe or persistent asthma in early childhood are predictors of asthma in adulthood. Data from the Melbourne Asthma Study suggested that mild asthma or infrequent wheezing associated with viral infections in childhood was not likely to progress to severe disease in adulthood. In this longitudinal cohort of approximately 500 subjects, data have been collected on the symptoms, growth, and lung function for more than 50 years.[12] Subjects were entered in the study at 7 years of age and were classified as never wheezed (controls), mild wheezy bronchitis, wheezy bronchitis, and asthma; a cohort with more severe asthma was added 3 years later. The loss of lung function seen in the groups with asthma and severe asthma by 10–14 years of age did not worsen over time. The rate of loss of lung function as measured by $FEV_1$ had the same rate of decline up to age 50 in all the groups, even after adjusting for smoking history. Moreover, asthma remission, defined as no symptoms and no medical treatment for 3 years, occurred in 64% of those with intermittent childhood asthma, 47% of those with persistent childhood asthma, and 15% of those with severe childhood asthma. Data from the Childhood Asthma Management Program (CAMP) also indicate that outcomes in children initially diagnosed with moderate asthma vary and are predicted by certain features.[13] During a 7- to 10-year follow-up period of 909 children initially enrolled in a 4-year-long clinical trial of placebo versus budesonide (BUD) versus nedocromil, 6% remitted, 39% had periodic asthma, and 55% had persistent disease. Prestudy factors associated with disease remission included lack of allergen sensitivity and exposure to indoor allergens, milder asthma, older age, less airway responsiveness (methacholine $PC_{20}$), and higher prebronchodilator $FEV_1$. Moreover, there was no effect on disease outcome by treatment. These results also highlight the lack of current antiinflammatory treatments' ability to alter disease natural history.

Studies of children with asthma based both on history and on assessment of pulmonary function indicate that many children who lose overt symptoms have persistent airway obstruction. Nonspecific airway hyperreactivity associated with asthma is present in formerly asthmatic patients who are free from clinical asthma.[14] Individuals who had asthma as children have a significantly lower $FEV_1$, more airway reactivity, and more frequent persistence of symptoms than those with infection-induced wheezing or the controls. In addition, 88% of the adults with childhood asthma who had persistent symptoms had positive methacholine challenge test results, as did 42% of the asymptomatic former asthmatics. The recurrence of overt asthma after years of freedom from symptoms is not unusual. Thus asthma is often a lifelong disease with periodic exacerbations and remissions, although laboratory evidence of decreased pulmonary function, airway inflammation, and airway hyperresponsiveness may persist, even when symptoms are quiescent.

In children and adolescents, asthma is frequently a completely reversible obstructive airways disease, and indeed no abnormalities in pulmonary functions can be detected in many asthmatic patients when they become symptom-free. However, recent studies that examine not only symptoms and pulmonary function but also indices of airway inflammation and bronchial hyperresponsiveness suggest that airway inflammation may persist in the absence of symptoms. In a study of 54 young adults (18–25 years of age) with atopic asthma or asthma in clinical remission (absence of symptoms for at least 12 months, median duration 5 years), subjects in remission were found to have evidence of airway inflammation and remodeling.[14] When compared with normal healthy controls, the subjects in remission had increased epithelial and subepithelial major basic protein and reticular basement membrane thickness; values were close to those of subjects with active asthma. Peripheral eosinophil counts were also elevated in the remission patients, and there was a significant correlation between basement membrane thickness, exhaled NO, and hyperresponsiveness to adenosine monophosphate. These findings indicate that the airways of some asymptomatic asthmatics, seemingly in clinical remission, may still show significant abnormalities and evidence of active inflammation. It is unclear that continued treatment in the face of absent symptoms will alter the natural history of the disease in these patients.

Asthma does appear to progress to chronic obstructive disease in some individuals, and features of asthma can be found in some adult patients with COPD (the so-called overlap syndrome).[6] The functional and structural causes of this irreversible airway obstruction variant of asthma are not understood. A process referred to as *airway remodeling* is often suggested as the cause of chronic obstruction and severe asthma, but data to conclusively support this hypothesis are lacking. It is believed that chronic mucous plugging, tracheobronchial ciliary dysfunction, smooth muscle and goblet cell hyperplasia, and collagen deposition in the lamina reticularis of the basement membrane occur as a consequence of persistent inflammation. Genetically determined dysregulation of inflammatory mediator production with or without repeated exposure to certain environmental stimuli may also play a role. Data from animal models demonstrate that even when inflammation is suppressed and changes consistent with remodeling are reduced markedly, airway hyperresponsiveness persists.[15] These data suggest that airway remodeling alone is probably not responsible for severe, irreversible airway obstruction or bronchial hyperresponsiveness.

The natural history of childhood asthma and the effects of aggressive long-term management on outcomes remain incompletely understood, but a great deal of data have come from the CAMP study.[16] CAMP was a well-designed comprehensive longitudinal study in which the primary objective was to compare the effects of long-term treatment (4 years) with an inhaled steroid (BUD) and a nonsteroidal treatment (nedocromil) to placebo in school-age children ($n = 1041$) with mild to moderate asthma. The hypothesis was that treatment with an inhaled steroid would result in better lung growth compared with no or lesser treatment.

Primary outcome was postbronchodilator $FEV_1$, but a wealth of other data on atopy, airway reactivity, symptoms, exacerbations, and linear growth was obtained. After a brief improvement in $FEV_1$ in the BUD group, there was no difference in $FEV_1$ between the groups over the last 3 years of the study. However, patients in the BUD group had decreased hospitalizations and urgent care visits compared with the placebo group. Patients in the nedocromil group also had fewer emergency visits but not hospitalizations, and both groups had less oral prednisone use. There was a small, transient decrease in growth velocity in the BUD group compared with the placebo and nedocromil groups. These data suggest that long-term treatment with inhaled steroids in school-aged asthmatics does not alter pulmonary function over time, even though the symptom control and airway reactivity improved. Failure to alter the natural history of asthma, as measured by lung function, in the CAMP study was thought in part to be caused by beginning treatment too late after the onset of disease. However, subsequent studies of inhaled steroid treatment (Fluticasone 88 μg twice a day) in younger children (2–3 years of age) who had recurrent wheezing and were at very high risk for developing asthma showed improvement in clinical symptoms and exacerbations compared with those receiving placebo. However, the treatment did not prevent clinical symptoms or alteration in lung function (measured by impulse oscillometry) in the subsequent year when treatment was stopped.[17] These data again indicate the inability of inhaled corticosteroids (ICSs) to modify the long-term disease state.

## Asthma Mortality

Despite the relatively high prevalence of asthma, mortality rates for childhood asthma are extremely low and have stabilized and actually decreased over the past decade.[2] This is evident when adjusting outcome metrics for the population at risk rather than the overall population.[18] Overall, fewer than 4000 individuals (of whom fewer than 150 are children) die of asthma in the United States each year. However, death rates are significantly higher in African Americans of all ages. Analyses of causes of death in children with asthma suggest that the major causes are the failure of the physician, parent, or patient to appreciate the severity of asthma, which results in inadequate or delayed treatment, poor access to health care, and the use of inappropriate medications (e.g., overreliance on β-adrenergic agonists and avoidance of use of corticosteroids). In fact, recent data from Costa Rica demonstrated that a 129% increase in the prescription of ICSs over a 7-year period was associated with an approximately 80% reduction in deaths due to asthma.[19] Labile asthma, regardless of severity, is also a risk factor, as are respiratory infections, nocturnal asthma, history of respiratory failure, and marked diurnal variation in air flow limitation. Some patients cannot perceive severe air flow obstruction, especially when it occurs gradually, and a small number may have sudden profound bronchospasm, which can be fatal. Other factors, such as exposure to allergens (mold), psychosocial disadvantage, poverty, previous episodes of respiratory failure, history of hypoxic seizure, previous admission to an intensive care unit, and psychological factors in both the patient and family have been implicated in deaths from asthma.

## Diagnosis of Asthma

An asthma diagnosis requires demonstration of episodic symptoms of air flow obstruction, which must be at least partially reversible, and alternative diagnoses should be excluded. Although airway hyperresponsiveness is an almost universal feature of asthma, it is not unique and therefore cannot be used as a defining characteristic. The methods to establish the diagnosis include a detailed medical history, a physical examination with a focus on the respiratory system, and performance of spirometry in children who are 5 years of age or older. A number of ancillary tests (e.g., allergy skin tests, inhalation or exercise challenge tests, home peak flow monitoring) may also be useful and, in some cases, necessary.

Although patients with asthma may present in a variety of ways, most have certain common historical features, such as intermittent or recurrent wheezing, an expiratory, musical, high-pitched, whistling sound produced by air flow turbulence in the large airways below the thoracic inlet. Many parents and even older children cannot accurately describe wheezing and may actually report stridor (from upper airway obstruction), stertor, snoring, or rhonchorous breathing. Careful explanation or even demonstration of wheezing is often necessary to obtain an accurate history. Wheezing can also be generated by adduction of the vocal cords and forceful inspiration and expiration. Inspiratory wheezing per se is not characteristic of asthma and suggests obstruction in the laryngeal area, such as that induced by croup or vocal cord dysfunction (VCD). However, wheezing also occurs during inspiration when asthma worsens and may disappear altogether as obstruction becomes more severe and air flow is limited. Asthma can occur without wheezing if the obstruction involves predominantly the small airways. Coughing or shortness of breath may be the only complaint. However, so-called cough-variant asthma may be overdiagnosed. Probably no more than 5% of asthmatic children have cough as the only or primary symptom, and the cough should resolve with appropriate asthma medications and recur when the medications are stopped. Older children often complain of a "tight" chest with colds, recurrent "chest congestion," or bronchitis. Usually, symptoms are more severe at night or in the early morning and improve throughout the day. A history of symptomatic improvement after treatment with a bronchodilator suggests the diagnosis of asthma, but a failure of response does not rule out asthma. When asymptomatic, many asthmatic children will have normal lung function ($FEV_1$). Reduction of the $FEV_1/FVC$ is considered to be a more reliable indicator of airway obstruction in children. An inhalation challenge test (e.g., methacholine or mannitol) should be performed when asthma is suspected but spirometry is normal or near-normal.

Family history is often positive for asthma or allergy (allergic rhinitis, eczema) in a first-degree relative. A history of personal allergy is found in more than two-thirds of children with asthma.

## Physical Examination

The physical examination should focus on overall growth and development; the condition of the entire respiratory tract including the upper airway, ears, and paranasal sinuses as well as the chest;

and other associated signs of allergic disease. Although severe asthma can adversely affect linear growth, this is not a common feature, and its presence should suggest evaluating for alternative causes of growth failure.

Unless acutely ill, examination of the lungs is frequently normal in children who are ultimately diagnosed with asthma. In some cases, particularly during periods with acute symptoms, auscultation reveals coarse crackles or unequal breath sounds, which may clear at least partly with coughing. If they persist, particularly during clinical stability, the possibility of another diagnosis should be considered. Although wheezing can often be elicited with a forced expiratory maneuver, occasionally there is only prolongation of expiration without wheezing. The older child or adolescent may resist exhaling forcefully to induce latent wheezes, because such a maneuver may induce coughing, which can increase bronchospasm. Some patients with severe asthma do not wheeze because too little air is moving to generate the sound. Wheezing from the lower respiratory tract should be differentiated from similar sounds that can emanate from the laryngeal area in even nonasthmatic children with sufficient forced expiration.

A variety of extrapulmonary signs indicating the presence of complicating factors or alternative diagnoses (e.g., allergy or cystic fibrosis) should be sought in all children being evaluated for asthma. Nasal polyps occur rarely in the child with uncomplicated asthma, and their presence suggests cystic fibrosis. However, nasal polyps can occur in highly allergic adolescents or those with aspirin sensitive asthma. Digital clubbing is not a feature of asthma; although clubbing may be a nonpathologic familial trait, its presence suggests cystic fibrosis, congenital heart disease, inflammatory bowel disease, or another chronic lung disorder. The conjunctivae should be examined for edema, inflammation, and tearing, suggesting allergy. Flexor creases and other areas of the skin should be examined for active or healed atopic dermatitis.

Hyperventilation and VCD syndrome should be considered in the differential diagnosis of the child with asthma that is apparently refractory to all therapy, especially if there are no symptoms during sleep. Both conditions are more likely to occur in adolescence or later childhood and may be mistaken for asthma, or may coexist with it. Typically the patient with hyperventilation is anxious and complains of marked dyspnea and difficulty getting enough air to breathe in spite of excellent air exchange on auscultation and an absence of wheezing. Often there are associated complaints of headache and tingling of the fingers and toes. Pulmonary function tests (PFTs) are helpful in differentiating hyperventilation syndrome from asthma; a normal spirogram during or around the time of symptoms is inconsistent with asthma. Immediate therapy consists of giving reassurance and having the patient rebreathe into a paper bag to elevate $PaCO_2$. VCD is another condition that must be differentiated from true asthma.[20] In these patients, wheezing is often a prominent feature, may occur on inspiration and expiration, and is typically loudest over the trachea or central, anterior chest. This condition is more common in older children, adolescents, and females, and it may also be seen in elite athletes. Most patients with VCD cannot voluntarily induce an episode, although in many patients, including highly trained athletes, exercise can precipitate an attack.[20,21] Although VCD was originally described in adults with psychiatric disorders, in children it is not usually associated with serious psychological disturbances and should not be labeled as such. The etiology in children remains poorly understood. The mechanism involves holding the anterior third of the vocal cords in a position of relative adduction during inspiration, but also in expiration. There may also be inward deflection of the supraglottic structures as well; this condition is sometimes called exercise-induced laryngomalacia (EILO). A recent study suggested that EILO in adolescence may be related to a diagnosis of clinically significant congenital laryngomalacia in infancy.[22] The result is loud, monophonic wheezing in a patient who has normal oxygen saturation and responds poorly to inhalation of a bronchodilating aerosol. Patients may appear comfortable or anxious in the face of loud wheeze. Pulmonary function testing may reveal a pronounced flattening of the inspiratory loop; however, since some patients with VCD also have true asthma, there may be evidence of large and/or small airway obstruction on the expiratory loop as well (Fig. 45.3). An increase in the mid–vital capacity expiratory/inspiratory flow ratio from the normal value of about 0.9 to a value of greater than 2 indicates extrathoracic obstruction consistent with VCD. It should be noted that most patients with VCD will have normal pulmonary function testing when asymptomatic. The diagnosis is confirmed by direct observation of paradoxical vocal cord movement via flexible laryngoscopy during an acute episode. Upper and lower airway examination with a flexible bronchoscope should be considered in patients with atypical reports of wheeze, dyspnea on exertion, or stridor to identify anatomic lesions such as cysts, hemangiomas, or laryngotracheomalacia. Older children with both VCD and asthma often can distinguish the "site" of the wheezing when the source of the problem is explained to them. The absence of nocturnal symptoms may also be a diagnostic clue that VCD is the diagnosis rather than asthma. Effective treatment consists of appropriate asthma medication (when an asthma diagnosis has been confirmed), treatment of aggravating conditions (reflux, rhinitis), and referral to a speech therapist or psychologist specializing in behavior modification in order to learn relaxation techniques and alternative breathing strategies. The vast majority of patients will improve with this treatment.

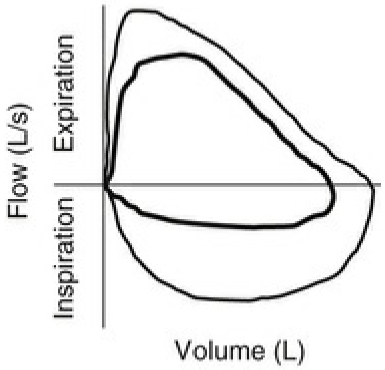

**FIG. 45.3** Flow-volume curve from a patient with vocal cord dysfunction. The thin line represents the flow at normal baseline. The thick line represents the flow during an obstructive episode and depicts a slight decrease in expiratory flow and a marked decrease in and flattening of the inspiratory loop.

## Asthma Triggers

Many older children will identify more than one precipitating factor responsible for asthma. Moreover, patterns of reactivity may change. Thus exercise-induced asthma (EIA) may not be viewed as a problem in many adolescents or adults with asthma who have learned in childhood that exercise induces symptoms and have developed a lifestyle that avoids exercise. Allergic factors that precipitated asthma in childhood may no longer cause symptoms in adolescence or adulthood, even though the patient continues to have asthma. Patterns also may change with treatment or the institution of environmental control measures. The use of quality-of-life questionnaires can help uncover latent symptoms and provide information that may be useful in identifying more subtle triggers.

## Allergens

In the majority of children with asthma, it is possible to induce an asthmatic reaction to substances in which IgE-mediated reaction is involved. Allergens that can induce asthma symptoms include animal allergens, mold spores, pollens, insects (cockroach), infectious agents (especially Mycoplasma and fungi), and occasionally drugs and foods. Cockroach and rodent allergens appear to be potent factors, particularly in inner-city children, and have been associated with increased health care utilization in children who are both sensitized and exposed to the allergens.[23] Allergic reactions may induce bronchoconstriction directly, may increase tracheobronchial sensitivity in general, and may be obvious or subtle precipitating factors. Bronchoconstrictor responses to allergens via IgE antibody–induced mediator release from mast cells generally occur within minutes of exposure, last for a relatively short period of time (20–30 minutes), and resolve. Such reactions are termed *early antigen* or *asthmatic responses.* It is the "late asthmatic response" (which occurs 4–24 hours after antigen contact) that results in more severe and protracted symptoms (lasting hours) and ultimately contributes to the chronicity and severity of the disease. The late response is due to inflammatory cell reactions and the release of multiple mediators, including IL-4, IL-5, and IL-13. Such allergen-induced dual responses can only be demonstrated in approximately half of all asthmatics challenged in a laboratory setting.

## Irritants

Numerous upper and lower respiratory tract irritants have been implicated as precipitants of asthma. These include paint odors, hairsprays, perfumes, chemicals, air pollutants, diesel particulates, tobacco smoke, cold air, cold water, and cough. Some allergens may also act as irritants (e.g., molds). Some irritants such as ozone and industrial chemicals may initiate bronchial hyperresponsiveness by inducing inflammation, yet they do not produce a late-phase response. Active and passive exposure to tobacco smoke, in addition to acting as a precipitant and aggravator of asthma, can also be associated with an accelerated irreversible loss of pulmonary function.

## Weather Changes

Atmospheric changes are commonly associated with an increase in asthmatic activity. The mechanism of this effect has not been defined but may be related to changes in barometric pressure and alterations in the allergen or irritant content of the air. Grass pollen, which in its native state is too large to enter the lower airways, fractionates into numerous small starch granules bearing allergen when exposed to water, such as during storms. These small particles, along with fungal spores (*Alternaria* or *Cladisporium*) and PM 2.5 particles readily enter the lower airways and can trigger severe acute asthma in susceptible individuals; the risk is particularly high when grass pollen counts exceed 20–50 grains/m$^3$. A recent outbreak of asthma deaths in Melbourne, Australia, following thunderstorms during periods of high grass pollen counts was attributed to this mechanism.[23a,23b]

## Infections

By far, the most common infectious agents responsible for precipitating or aggravating asthma are viral respiratory pathogens.

It is estimated that up to 85% of asthma exacerbations in school-aged children are due to viral infections, and rhinovirus has emerged as a prominent pathogen in causing acute asthma.[24] Among the three serotypes of rhinovirus, infection with hRV-C is more likely to be associated with acute asthma exacerbations than infection with hRV-A or hRV-B. In addition, there is some evidence that rhinovirus, detected in nasal lavage, can cause an increase in daily asthma symptoms apart from significant exacerbations.[25] In some instances, bacterial infections (e.g., pertussis or mycoplasma) and, more rarely, fungal infections or colonization (e.g., bronchopulmonary *Aspergillosis*) and parasitic infestations (e.g., *Toxocariasis* and *Ascariasis*) can be triggers. The mechanisms of viral-induced exacerbations are incompletely understood, but probably involve some direct respiratory epithelial injury caused by infection, alteration of host inflammatory responses driven by the infection, and influence of other cofactors (concomitant allergen exposure or mediator production). For instance, it is clear that children who have significant respiratory viral–induced wheezing are more likely to have elevated IgE and allergen sensitization.[26] In addition, asthmatics may have decreased production of interferons type I, II, and III, which can be associated with decreased airway function.

## Exercise

Strenuous exercise (i.e., exercise sufficient to cause breathlessness and hyperventilation) may induce bronchial obstruction in as many as 90% of individuals with persistent asthma; this phenomenon is termed *exercise-induced bronchospasm (EIB)*. In addition, exercise can cause significant bronchospasm in up to 40% of individuals with allergic rhinitis who do not have persistent asthma. When otherwise normal individuals develop bronchoconstriction in response to exercise with hyperventilation, it is often termed *EIA;* this may occur in 10%–13% of the general population. Symptoms induced by exercise range from subtle (mild dyspnea) to significant coughing, wheezing, and excessive breathlessness. Symptoms typically begin after 5–10 minutes of vigorous activity and are most prominent after activity ceases (by contrast with VCD/EILO, in which symptoms come on during exercise). The mechanisms underlying EIA remain somewhat uncertain. Recent data indicate that hyperventilation of cold, dry air causes heat and water loss from the airways, producing a hyperosmolar lining fluid and injuring the airway epithelium. Induced sputum obtained from individuals with EIB demonstrates columnar epithelial cells, eosinophils, and increased concentrations of leukotrienes. There is also cytokine release from neutrophils.[27] Cooling of the airways has also been described to result in vascular congestion and dilatation in the bronchial circulation. The subsequent mucosal swelling as a result of vascular congestion and edema produces airway narrowing. Symptoms of EIB usually resolve spontaneously within 1 hour after ceasing exercise, but may require treatment with a short-acting β agonist (SABA) for complete resolution. There is typically a refractory period of 1–3 hours following an episode of EIA/EIB, during which further exercise will not cause significant bronchospasm. Although studies are conflicting, there is generally not a late-onset response (8–12 hours postexercise) following the immediate reaction. A recent study of a cohort of Swedish adolescents, aged 13–15 years, who underwent exercise challenge tests and continuous exercise laryngoscopy testing showed that the prevalence of EIB was 19.2%, the prevalence of EILO was 5.7%, and 5% had both conditions. Of note, 49.4% of those who complained of exercise-induced dyspnea had neither condition.[28] EIA may be both underdiagnosed when symptoms are subtle, or it may be overdiagnosed or misdiagnosed due to a number of masquerading conditions (e.g., VCD, EILO, poor conditioning, or cardiac dysfunction).

## Emotional Factors

Emotional upsets clearly trigger asthma in some individuals; however, there is no evidence that psychological factors are the basis for asthma. Coping styles of patients, their families, and their physicians can intensify or lead to more rapid amelioration of asthma. Conversely, denial of asthma by patients, parents, or physicians may delay therapy to the point that reversibility of obstruction is more difficult. Psychological factors have been implicated in deaths from asthma in children. The influence of psychosocial factors on compliance is yet another important factor related to treatment failure or success. Asthma itself can strongly influence the emotional state of the patient, the family, and other individuals associated with the patient. In addition, some studies indicate that psychosocial stressors, both internal (lack of parental support) and external (witnessing violence), may modulate immune responses, increase inflammation, or decrease steroid responsiveness, leading to poorer asthma control.[29,30]

## Gastroesophageal Reflux

Reflux of gastric contents into the tracheobronchial tree can aggravate asthma in children and is one of the causes of nocturnal asthma. Typical symptoms of gastroesophageal reflux (GER)—heartburn, chest pain, regurgitation, sour brash—may be absent in many children with asthma; estimates are that reflux may be "silent" in more than 50% of asthmatic patients. Pediatric studies have reported a prevalence of GER between 19% and 80%, with a mean of about 22%.[31] However, due to methodological flaws and absence of longitudinal studies, a clear association between GER and asthma symptoms in children remains unclear. Although the exact extent to which reflux exacerbates asthma remains controversial, it is clear that acid (or even nonacid) reflux of gastric contents into the distal esophagus can lead to cough and bronchospasm, presumably via increased vagal activity. Aspiration of gastric contents in even micro amounts is also presumed to cause bronchial irritation and bronchospasm. Data from a large double-blind clinical trial in children did not show benefit to improving any aspect of asthma control with treatment with proton pump inhibitor (PPI) in asthmatic patients who did not have symptoms of GER.[32] In addition, the data support possible adverse effects in the form of increased respiratory infections and symptoms in some children with asthma treated with lansoprazole.[33]

## Allergic Rhinitis and Sinusitis

Acute or chronic sinusitis can be associated with aggravation of asthma and can be a cause of recalcitrant asthma. In some patients, asthma and sinusitis occur at the same time; the nasal symptoms from the sinusitis may make cough and other symptoms of asthma worse and less responsive to bronchodilator therapy alone. The upper airway may be viewed to some extent as a continuum of the lower airway; inflammatory mediator release in the lower airway may be triggered as a response to sinus infection. This subject is discussed in more detail in Chapter 47.

## Nonallergic Hypersensitivity to Drugs and Chemicals

Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen, can exacerbate asthma in selected individuals by increasing production of 5-lipoxygenase metabolites, including leukotrienes. The typical aspirin-sensitive asthmatic has nasal polyps, urticaria, and chronic rhinitis. Aspirin ingestion may diminish pulmonary function and produce wheeze, cough, rhinitis, conjunctivitis, urticaria, and angioedema in 10%–20% of adults with asthma.[34] Although more common after the third decade of life, the prevalence in children (as determined by a decrease in $FEV_1$ of at least 20% from baseline following aspirin or NSAID ingestion) has been reported to be as high as 5% when determined by direct challenge testing. Although aspirin in particular is rarely given to children and adolescents because of the risk of Reye syndrome, there is a very high cross-reactivity to common NSAIDs in aspirin-susceptible patients. High-dose acetaminophen may also cause wheezing in a small portion (<2%) of aspirin-sensitive asthmatics. Some (but not all) studies suggest that early-life use of acetaminophen may increase the risk of developing asthma, and one large trial found a reduced risk of an acute care visit for asthma following treatment with ibuprofen compared with treatment with acetaminophen.[35] However, the data are more compelling for prenatal exposure to acetaminophen and development of asthma. Moreover, some studies are “confounded by indication,” and when adjusted for the incidence of respiratory tract infection, the risk of developing asthma is greatly attenuated.[35,36] The absence of a history of increased symptoms following NSAID ingestion in asthmatic children is generally sufficient to warrant safe use of NSAIDs as needed. A recent trial comparing acetaminophen use with ibuprofen in children aged 1–5 years found no difference in the incidence of asthma exacerbations.[37] However, aspirin/NSAID sensitivity should be considered in children and adolescents with severe or difficult-to-control asthma, who also have chronic rhinitis, urticaria, and nasal polyps.

Metabisulfite has been reported as a precipitant or aggravator of asthma, both by allergic and nonallergic mechanisms. Sensitive individuals should avoid foods containing or preserved using sulfites (e.g., shrimp, dried fruit, beer, and wine).

## Endocrine Factors

Aggravation of asthma and increased pulmonary function variability occurs in some adolescent and adult women in relation to the menstrual cycle, beginning shortly before menstruation and ending shortly after the onset of menses.[38] Whether this reflects changes in water and salt balance, irritability of bronchial smooth muscle, or other factors is unknown. The use of the oral contraceptive pill has been reported to both aggravate and ameliorate premenstrual asthma. Hyperthyroidism has been reported to worsen or precipitate asthma in an occasional patient, and treatment of hyperthyroidism usually ameliorates the asthma.

Vitamin D deficiency has gained increasing attention as a possible contributor to both the development of asthma and a contributor to its control. Data from the National Health and Nutrition Examination Survey (NHANES) study indicated a direct relationship between serum vitamin D concentration and $FEV_1$/FVC. In addition, several studies demonstrate lower vitamin D levels in African Americans, Hispanics, and obese individuals, all groups with increased risk for higher asthma morbidity. Among asthmatic children, vitamin D insufficiency (defined as serum concentration $\leq$30 ng/mL) occurs in approximately one-third of those studied.[39] Among 1024 participants in the CAMP study, 35% were vitamin D insufficient at study entry. This group had an increased risk of severe asthma exacerbation (OR 1.5, 1.1–1.9, $P = .01$) during the 4 years of the study, after adjusting for numerous factors (i.e., age, sex, body mass index [BMI], and treatment group). Those in the BUD treatment group had an even greater effect (OR 1.8, 1.0–3.2, $P = .05$). These results are similar to those described for a cohort study ($n = 616$) of asthmatic Costa Rican children, 28% of whom were vitamin D insufficient. Serum vitamin D was inversely associated with serum IgE and peripheral eosinophil count. In addition, higher vitamin D levels were associated with a significant decrease in risk of hospitalization in the previous year, a decrease in the use of antiinflammatory medicines, and borderline decreased airway hyperresponsiveness. The mechanisms by which vitamin D influences asthma expression remain unclear, but there are many possibilities. Vitamin D suppresses bronchial smooth muscle mass and goblet cell hyperplasia, and serum concentrations are inversely associated with the frequency of viral respiratory infections. Vitamin D treatment of T reg cells from steroid-resistant asthmatics resulted in increased production of the antiinflammatory cytokine IL-10 with steroid stimulation and also reduced IgE production from human peripheral B cells.[40] Moreover, it has also been speculated that polymorphisms in the vitamin D receptor play a role in asthma, but data are inconsistent. Several clinical trials to demonstrate efficacy of vitamin D in asthma treatment have been performed in children and adults. In a study of vitamin $D_3$ supplementation in adults with persistent asthma vitamin D insufficiency, the rate of first treatment failure or exacerbation was not reduced.[41] Data in children are more mixed, with some studies showing modest effect on exacerbation reduction but little effect on other clinical outcomes.[42] Further research is needed to substantiate the role of vitamin D in asthma pathophysiology.

## Nocturnal Asthma

There is a circadian variation in airway function and bronchial hyperresponsiveness in most patients with asthma. In individuals with a normal sleep-wake cycle, the worst peak expiratory flow rate (PEFR) and the most pronounced reactivity occur at approximately 4 a.m., and the best occur at 4 p.m. Nocturnal asthma is a risk factor for asthma severity and even death in some asthmatics. Although nocturnal asthma may result from late-phase reactions to earlier allergen exposure, GER, or sinusitis in some patients, these conditions are not present in most patients with severe nocturnal asthma. Another explanation is an increase in inflammatory cell infiltrate as an exaggerated normal circadian variation. Abnormalities in central nervous system control of respiratory drive, particularly with defective hypoxic drive and obstructive sleep apnea, as well as physiologic increases in airway parasympathetic tone, reduction in lung volume, and airway smooth muscle unloading may also be present in some patients with nocturnal asthma. Recent work suggests that those with African ancestry who are obese and have lower lung function may be at increased risk for nocturnal asthma and reported a twofold increase compared to European Caucasian counterparts.[43]

## Laboratory Diagnosis

A number of laboratory studies may be useful in confirming the diagnosis of asthma, and objective measures of pulmonary function are among the most important.

## Lung Function Tests

PFTs, particularly spirometry, are objective, noninvasive, and extremely helpful in the diagnosis and follow-up of patients with asthma. Examination of the forced vital capacity (FVC), $FEV_1$, and forced expiratory flow rate over 25%–75% of the FVC ($FEF_{25-75}$) is a reliable way to detect baseline airway obstruction. Examination of the volume-time curve and shape of the flow-volume loop provides an estimate of the adequacy of the patient effort in performing the test. A PFT should be attempted on all children older than 5 years of age when considering the diagnosis of asthma. However, there is some controversy regarding the value of repeated measures of lung function compared with symptom report in improving asthma outcomes.[44] Nevertheless, attempting to achieve and maintain normal or near normal lung function is a goal for all asthmatic children.

In children, measurement of $FEV_1$ alone may miss airway obstruction; the $FEV_1$/FVC has been proposed as a more sensitive measure of obstruction. $FEF_{25–75}$ has been proposed as a more sensitive indicator of airway obstruction, in the small airways in particular, and a better indicator of a response to bronchodilators and airway hyperresponsiveness than either $FEV_1$ or FVC. However, recent data indicate that this information is not entirely accurate. The $FEF_{25–75}$ is a highly variable measure that is readily influenced by expiratory time and change in FVC. Examination of large data sets including children with asthma and cystic fibrosis indicates that less than 3% of the test results showed a reduced $FEF_{25–75}$% with both $FEV_1$/FVC and FVC within the normal range.[45] Documentation of reversibility of air flow obstruction following inhalation of a bronchodilator is central to the definition of asthma. If obstruction is demonstrated on a baseline PFT, a bronchodilating aerosol (albuterol) should be administered and the PFT repeated in 10–20 minutes. An improvement of at least 12% and 200 mL in the $FEV_1$ is considered a positive response and is indicative of reversible air flow obstruction; however, in children, an improvement of 10% may be adequate to indicate significant improvement. A 10% improvement in the percent predicted $FEV_1$ is also considered a positive response.

Use of a peak flow meter in the office setting may provide some useful information about obstruction in the large central airways, but the test should not be used to diagnose asthma. PEFR is extremely effort-dependent and is only reflective of obstruction in the large central airways.

Although standard spirometry has long been considered the gold standard for use in diagnosing and monitoring change in airway function in patients with asthma, other modalities may have particular application in both younger and older children. Forced oscillation capitalizes on the resonant oscillation properties of the airways to measure conductance and reactance and, indirectly, airway resistance.[46] The technique requires only tidal breathing on a mouthpiece for 30 seconds in order to obtain a measurement; response to a bronchodilator can also be detected. In some studies, area of reactance (AX) as measured by forced oscillation was able to discriminate those with asthma, even when $FEV_1$ was not different between the two groups.[47] Widespread adoption of forced oscillation techniques has not occurred largely due to lack of reliable normative values.

## Bronchial Challenge Tests

Airway hyperreactivity to substances such as methacholine, histamine, hypertonic saline, adenosine monophosphate, or mannitol forms the basis of an adjunctive diagnostic test for asthma (Video 45.2▶). However, the sensitivity and specificity of the tests vary widely, and bronchoprovocation testing cannot serve as the sole determinant of an asthma diagnosis. Methacholine and histamine are considered direct bronchoprovocation agents because they act directly on smooth muscle. Direct bronchoprovocation challenge testing with methacholine is very sensitive and has a better negative than positive predictive value. As such, it is generally more helpful in excluding than diagnosing asthma because positive results may be seen in disorders such as cystic fibrosis, COPD, chronic bronchitis, allergic rhinitis, and even in some normal individuals. $FEV_1$ is the primary measure used to assess response, and the concentration of methacholine at which a 20% decrease in $FEV_1$ occurs is recorded ($PC_{20}$); other methods use the cumulative dose ($PD_{20}$). A $PC_{20}$ of $\leq 4$ mg/mL is considered a positive test result indicative of airway hyperreactivity. However, there is no universally accepted threshold $PC_{20}$ value that is considered diagnostic of asthma (Table 45.1). Accurate interpretation must account for degree of baseline obstruction (if any), the pretest probability of asthma, the presence of current symptoms, and the degree of recovery in postchallenge $FEV_1$. Mild transient adverse effects (i.e., cough, wheezing, chest tightness, and dizziness) are uncommon and occur in less than 20% of patients receiving either histamine or methacholine challenge. Delayed or prolonged reactions are extremely rare, and fatalities after methacholine have not been reported. However, methacholine (or any bronchoprovocation test) should not be performed if the baseline $FEV_1$ is low (generally less than 60% predicted).[48]

### Table 45.1

**Interpretation of Methacholine Challenge Test Results**

| $PC_{20}$ (mg/mL) | Suggested Interpretation |
|---|---|
| <1.0 | Moderate to severe reactivity (asthma likely) |
| 1–4 | Mild reactivity |
| 4–16 | Borderline reactivity |
| >16 | Normal (no significant reactivity; asthma unlikely) |

Assumes that there is no baseline airway obstruction and that postchallenge improvement to baseline forced expiratory volume in 1 second occurs.

Indirect bronchoprovocation agents (i.e., hypertonic saline, adenosine monophosphate [AMP], mannitol) act by inducing release of inflammatory mediators in the airway, which then cause bronchoconstriction. In addition, indirect testing is well correlated with the degree of airway inflammation. Inhalation testing with dry-powder mannitol has good validity, and a commercial kit is approved for use in Europe, Australia, and the United States. Mannitol has the advantage of being safe and easy, and it requires no special equipment apart from a spirometer. A cut point of 15% decrease in $FEV_1$ from baseline had a specificity of 98% but a sensitivity of only 58%.[49] Other agents such as allergens and occupational sensitizers have been used for inhalation challenge tests, but such challenges may pose significant risk and should only be performed by experienced physicians and investigators in the context of specific clinical or research settings. Indeed, bronchial challenge tests with any inhaled agents should only be performed in certified pulmonary function laboratories under the direct supervision of a trained specialist.

## Exercise Challenge Test

In individuals 6 years of age through adulthood, a treadmill or bicycle ergometer exercise test provides useful information about the presence of EIB or EIA. In children with histories suggestive of EIB, an exercise challenge test is a more useful diagnostic aid than a methacholine challenge test (Video 45.3). The inhaled air should be dry, and the child should exercise at maximal level for 4–6 minutes and for a total time of 6–8 minutes. Maximal exercise is usually determined by heart rate (80%–90% of age maximum) or maximum voluntary ventilation ($FEV_1$ × 35); the target should be reached relatively quickly. Pulmonary function should be measured 5 minutes before exercise. Following exercise, serial pulmonary function measurements should be obtained for at least 20 minutes (at 5, 10, and 20 minutes postexercise) to determine the presence and severity of EIA. A decrease in $FEV_1$ of more than 10% is diagnostic of exercise-induced bronchoconstriction; some sources suggest a threshold of 15% decrease.[48]

# Other Tests

## Complete Blood Cell Count

Often the complete blood cell count is normal and offers little information in the diagnosis or management of asthma and may be most useful when searching for other complicating conditions (e.g., immunodeficiency states) rather than as a primary diagnostic aid.

However, eosinophilia, if present, most commonly suggests asthma, allergy, or both. Although there are other causes of peripheral eosinophilia in children (i.e., gastrointestinal or systemic eosinophilic disorder, parasitic infection, malignancy, and human immunodeficiency virus infection), asthma and allergy are the most likely causes. There has been renewed interest in using peripheral eosinophil count to both suggest an asthma diagnosis as well as to assign asthma phenotype.[50] Elevated blood eosinophil counts are not always associated with atopy, but there are data to support that eosinophil counts of 400/μL and above are more strongly associated with atopic asthma.[51]

## Cytologic Examination of Sputum

Obtaining induced sputum by inhaling hypertonic saline aerosols generated by an ultrasonic nebulizer is a useful technique for helping identify active inflammation in the airways characteristic of asthma. The presence and number of eosinophils and other inflammatory cells can provide useful information about disease phenotype, activity, and response to therapy.[52] Improved asthma control and reduced exacerbations were noted when there were less than 3% eosinophils in the induced sputum of adult asthmatics, but results in children are not consistent.[53,54] Neutrophilic inflammation predominates in some patients, while others have a paucity of inflammatory cells. Using cluster analysis in a study of adults enrolled in the Severe Asthma Research Program, over 80% of those in clusters with more severe asthma refractory to treatment with high-dose inhaled steroids and those with lower lung function had sputum neutrophilia.[55] Those in clusters with mild to moderate atopic disease had either eosinophilia or minimal inflammatory cells of any type. However, data from a small study of children with more severe asthma showed that the absence of blood eosinophilia did not predict absence of eosinophils in induced sputum or bronchoalveolar lavage (BAL).[56] Although the technique of obtaining induced sputum is relatively simple, it does require trained personnel, use of an established protocol, and specimen processing and is usually only successful in children that are at least 8 or 9 years of age. However, a recent report demonstrated success in obtaining induced sputum samples in children as young as 7 months using physical activity (or crying) followed by oropharyngeal suctioning to obtain the sample; 96% of 72 children aged 7–76 months were able to produce a sample.[57]

## Exhaled Nitric Oxide

NO is an important and widespread regulatory molecule that has diverse biological functions. NO is synthesized from L-arginine by three different forms of the enzyme NO synthase (NOS): constitutive forms—endothelial NOS (eNOS) found in endothelial cells and nNOS in neuronal tissue—and an inducible form, iNOS. Although the precise role of NO in the asthmatic airway remains uncertain, NO can function as a bronchodilator, has antimicrobial properties, has antiproliferative action on fibroblasts, and is involved in regulation of ciliary beat frequency and epithelial ion transport.[52] Fractional exhaled NO (FeNO) monitoring has been proposed as a biomarker useful in asthma diagnosis, monitoring control and adjusting treatment, and predicting exacerbations. In many but not all asthma patients, high exhaled NO concentrations, compared with the nonasthmatic, coupled with a reduction with inhaled steroid treatment suggest an active or counterregulatory role in the development or persistence of asthma. Most data support direct correlation between clinical markers of eosinophilic airway inflammation or atopy and FeNO, including the degree of airway hyperresponsiveness as measured by methacholine challenge.[52,58,59] Other measures (e.g., $FEV_1$, bronchodilator response, and symptom report) correlate only weakly with FeNO. In a study of 128 school-aged children with asthma and allergic sensitization, mean FeNO levels were significantly different between those children with no sensitization and those children with 1–3, 4–5, and ≥6 positive skin prick tests.[60] In addition, those sensitized to cat, mouse, dust mite, rat, and cockroach had FeNO levels that were significantly higher compared with those who were not sensitized. After adjustment for age, sex, ICS use, and asthma control level, cat and rat allergen remained significant independent predictors of elevated FeNO.

Although FeNO has proved of value in some situations and patient populations, a number of limitations exist.[61] Weaknesses include poor ability to identify noneosinophilic inflammation and lack of specificity for asthma. Elevated FeNO also occurs in individuals with allergic rhinitis, eosinophilic bronchitis, COPD, and lung allograft rejection.

The determination of clinical cutoff points for diagnosing asthma, adjusting treatment, and predicting exacerbations remains controversial. FeNO levels are affected by many factors, including, race, age, ingestion of nitrate rich foods (raises), and tobacco smoke exposure (lowers). If other clinical conditions associated with elevated FeNO are excluded, a FeNO higher than documented clinical cutoffs (Table 45.2) can be useful in supporting a diagnosis of asthma.[62] The common presence of atopy in children apart from asthma limits FeNO as an accurate diagnostic tool.

**Table 45.2**

**Range and Interpretation of Fractional Exhaled Nitric Oxide Values in Adults and Children. Symptoms Refer to Cough and/or Wheeze and/or Shortness of Breath**

| | **FeNO < 25 ppb (<20 ppb in Children)** | **FeNO 25–50 ppb (20–35 ppb in Children)** | **FeNO > 50 ppb (>35 ppb in Children)** |
|---|---|---|---|
| **DIAGNOSIS** | | | |
| Symptoms present during past 6 + weeks | Eosinophilic airway inflammation unlikely<br>Alternative diagnoses<br>Unlikely to benefit from ICS | Be cautious<br>Evaluate clinical context<br>Monitor change in FeNO over time | Eosinophilic airway inflammation present<br>Likely to benefit from ICS |
| **MONITORING (IN PATIENTS WITH DIAGNOSED ASTHMA)** | | | |
| Symptoms present | Possible alternative diagnoses<br>Unlikely to benefit from increase in ICS | Persistent allergen exposure<br>Inadequate ICS dose<br>Poor adherence<br>Steroid resistance | Persistent allergen exposure<br>Poor adherence or inhaler technique<br>Inadequate ICS dose<br>Risk for exacerbation<br>Steroid resistance |
| Symptoms absent | Adequate ICS dose<br>Good adherence<br>ICS taper | Adequate ICS dosing<br>Good adherence<br>Monitor change in FeNO | ICS withdrawal or dose reduction may result in relapse<br>Poor adherence or inhaler technique |

A number of studies have used FeNO to adjust treatment with inhaled steroids with mixed results.[63–65] A large trial conducted in largely black and Hispanic children compared adding FeNO to usual care (Expert Panel Review [EPR] 2 guideline) in children aged 12–20 years.[63] All participants improved during the run-in period, probably related to the use of guideline care by specialists and the direct provision of medication to the child. In the intervention period, using symptom days and exacerbations as outcomes, no differences between usual care and FeNO groups were noted; but the use of FeNO resulted in higher doses of ICSs.

In a relatively small study done in seven Belgian hospitals, children aged 5–14 years with allergic asthma were randomized to a group managed with symptoms and FEV1 or FeNO.[64] In the

FeNO group, a single target value of 20 ppb was used to increase treatment (>20 ppb) or lower treatment (≤20 ppb). In a 1-year follow-up period, there was no difference between the groups in the primary outcome of symptom free days, but there was a significant decrease in exacerbations. However, the exacerbations were largely related to an increase in symptoms and unscheduled medical contact; there was no difference in emergency visits or hospitalizations. A recent meta-analysis suggested that using FeNO to guide treatment decisions has little clinical benefit, although this may result in a decrease in asthma exacerbations.[65]

Commercial devices are available that permit the rapid, noninvasive, and easy measurement of eNO (in parts per billion, ppb) and are priced in the same range as a desktop portable spirometer.[61,67] Although somewhat easier to perform than standard spirometry, children younger than 6 or 7 years of age are not consistently able to perform an online FeNO measure; however, offline collection methods using tidal breathing and Mylar collection bags have been used in younger children and infants.

A number of studies have demonstrated the presence of a variety of inflammatory mediators in the liquid condensate from cooled exhaled air collected over a number of minutes. Cytokines, leukotrienes, nitrates, and other substances have all been reported in exhaled breath condensate (EBC), and in some but not all studies, they correlate with asthma disease activity.[68] In addition, an acid pH in the EBC has also been reported to be a marker of airway inflammation. More recently, devices that measure volatile organic compounds in exhaled breath, so-called electronic noses, have been used to discriminate airway and lung disease states, including asthma. These devices capitalize in part on measuring metabolomic airway products that provide a selective “breath print” that identifies asthma phenotypes.[69] However, there is still great controversy over standardization of the technique, the derivation of the measured substances (sampling of airway lining fluid rather than volatilized molecules), and the measurement of mediators. EBC has yet to prove useful as a noninvasive measure of airway inflammation, and it is currently a research tool.[70]

## Serum Tests

Determining quantitative levels of immunoglobulin G (and subclasses), M, and A is useful only to rule out immunodeficiency syndromes in children with recurrent or chronic infection. In children with asthma, IgG levels usually are normal, IgA levels are occasionally low, and IgM levels may be elevated. Systemic steroids, however, can depress IgG and perhaps IgA levels. Total serum IgE is often elevated in the child with asthma, atopy, or both; however, a normal IgE does not rule out asthma as a cause of symptoms. Although a rare condition in pediatric patients, in the child with shifting pulmonary infiltrates, a marked elevation of serum IgE (>1000 IU/mL) should prompt tests for both IgG and specific IgE antibody to *Aspergillus* to evaluate for allergic bronchopulmonary aspergillosis (see Chapter 65).

## Sweat Test

A sweat test (determination of chloride concentration in sweat) should be considered in children with chronic, otherwise unexplained, respiratory symptoms, including recurrent wheezing, to rule out cystic fibrosis, even in areas where newborn screening for the disease is carried out (discussed later). Associated signs and symptoms that should prompt a sweat test include poor weight gain and short stature, steatorrhea, nasal polyps, pansinusitis, hemoptysis, and digital clubbing. Newborn screening for cystic fibrosis is now universal in the United States, and most cases of cystic fibrosis are diagnosed in infancy or the preschool years, but screening does have a false negative rate of approximately 5%, depending on the cutoff values and the methods chosen. Mutations conferring pancreatic sufficiency, and other rare mutations are typically associated with milder pulmonary disease and may present much later than infancy (see Chapter 50).

## Radiographs

Most children with suspected asthma should have a chest radiograph at some time to rule out parenchymal disease, congenital anomaly, and (direct or indirect) evidence of a foreign body, particularly if the asthma diagnosis is questionable. However, a normal chest radiograph does not rule out other diagnoses, particularly a retained airway or esophageal foreign body. A chest radiograph should be considered for the child admitted to a hospital with asthma, particularly if there are localized findings on physical examination (i.e., crackles, egophony, diminished breath sounds), fever, or persistent hypoxemia. Radiographic findings in asthma may range from normal to hyperinflation with peribronchial interstitial markings and atelectasis (Fig. 45.4A); infiltrates, atelectasis, pneumonia, or a combination of the three (see Fig. 45.4B); and pneumomediastinum (see Fig. 45.4C), often with infiltrates. Pneumothorax occurs rarely (see Fig. 45.4D).

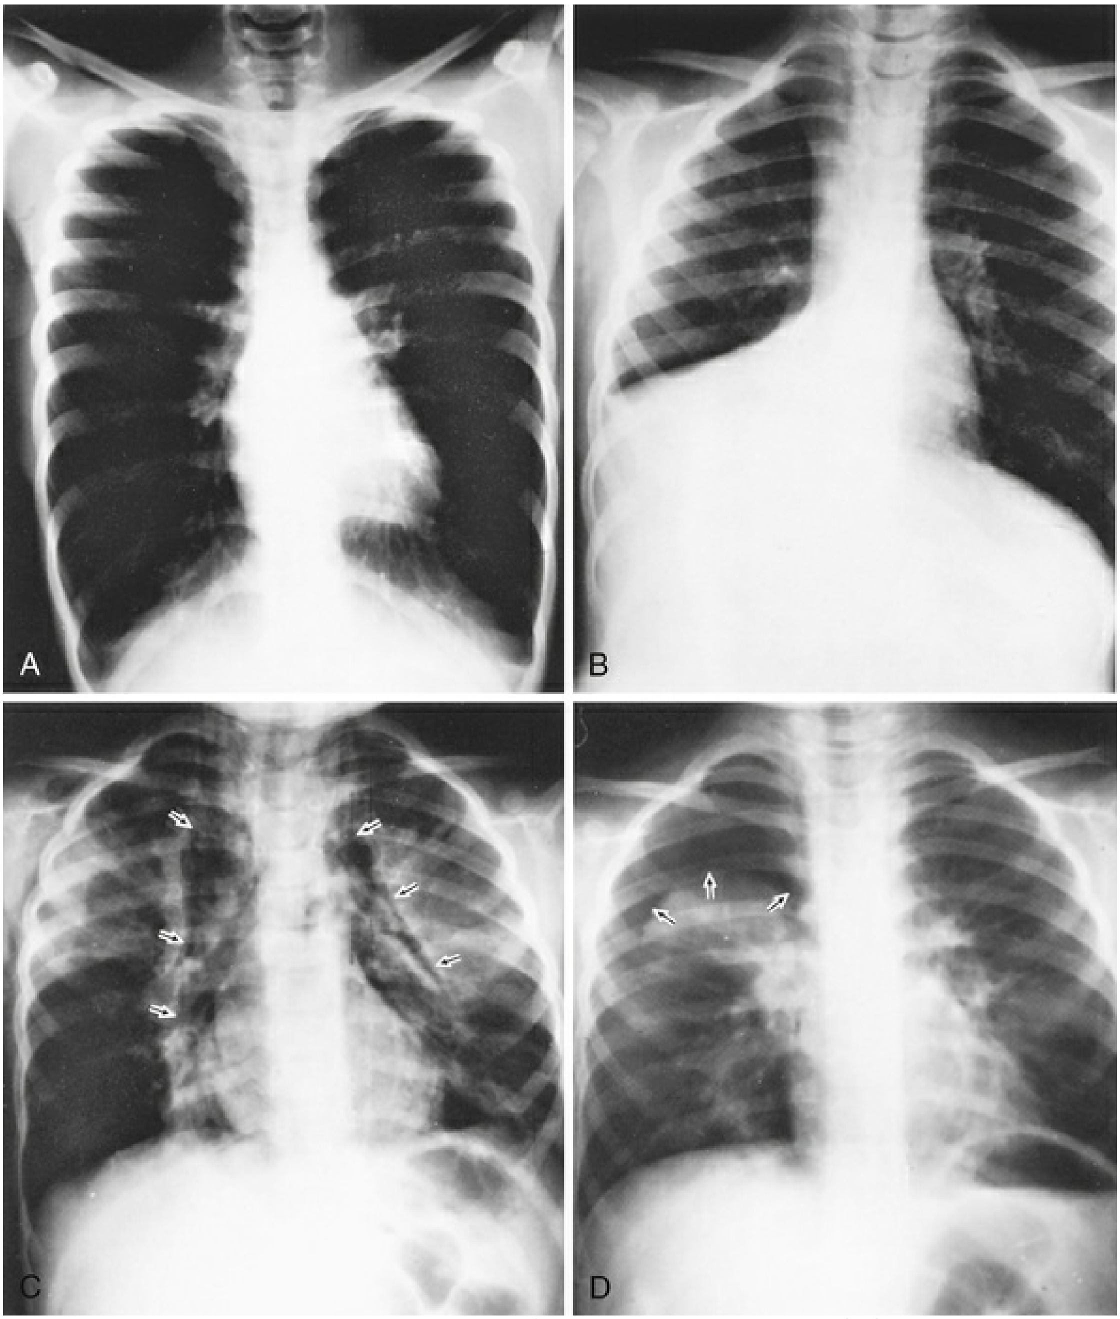

**FIG. 45.4** Radiographic findings in asthma. (A) Hyperinflation with increased bronchial markings. (B) Atelectasis involving a complete lobe. (C) Massive pneumomediastinum complicating asthma. (D) Pneumothorax secondary to paroxysmal coughing in asthma. *Arrows* mark air in (C), lung margin in (D).

Paranasal sinus radiographs or screening sinus computed tomography can also be considered for children with persistent nocturnal coughing, nasal symptoms, and headaches. Although acute and chronic rhinosinusitis have long been associated with an increase in symptoms in children with asthma, a recent study indicates that long-term treatment with nasal corticosteroids did not improve asthma control.[71] In a 24-week placebo controlled trial of daily intranasal mometasone, children with asthma and symptoms of rhinosinusitis did not show improvement in asthma control or reduction in exacerbations compared to placebo. Nasal symptoms did improve, but the study results argue against treating nasal symptoms to improve asthma control.

## Allergy Testing

Allergy testing (skin testing or in vitro serum allergen-specific IgE measure) is indicated in patients in whom specific allergic factors are believed to be important and in all children with severe asthma. Numerous allergic factors that might contribute significantly to the asthma (e.g., pollen, mold, dust mite, cockroach, or dander from domestic animals) occur in the home or at school. After taking a detailed environmental history, skin testing should be performed (usually percutaneous or scratch), limited to the most likely allergens, as suggested by the history.

Skin test results may vary with age, drug therapy, and inherent skin factors. Drugs that affect skin test results include $H_1$ antihistamines (which may inhibit skin reactions for up to 72 hours or longer), tricyclic antidepressants, and some histamine ($H_2$) blockers. Topical and systemic corticosteroids or montelukast do not affect skin reactions. Positive (histamine) and negative (saline) control tests should be included to detect inherent skin factors that may affect the reaction to allergen, such as dermatographism and extensive dryness or eczema.

The in vitro measure of allergen-specific IgE (s-IgE) makes use of the affinity of serum IgE antibody for antigen that has been bound to a solid phase substrate. The s-IgE is no more specific than the antigen employed, but it can produce a quantitative result, thus allowing the degree of sensitization to be measured. The s-IgE test is significantly more expensive than skin testing, but it can be performed in commercial laboratories and is useful for situations in which skin tests are impractical (e.g., for the patient with generalized dermatitis or dermatographism, or if the patient must continue to receive medications with antihistaminic activity) or to better quantify the degree of allergic sensitization (higher value of s-IgE).

## Therapeutic Considerations

Both the most recent US guidelines for the diagnosis and management of asthma (Expert Panel Report 3) and the international Global Initiative for Asthma (GINA) guidelines stress the importance of asthma control as compared with severity.[1,72] Asthma severity refers to the intrinsic intensity of the disease and is typically assigned prior to beginning treatment with controller medications, and is also reassessed at intervals after treatment to determine degree of responsiveness to treatment. As a result, severity becomes defined by the level of treatment necessary to achieve and maintain adequate control. Identifying children and adolescents with severe or therapy resistant asthma is important because the need for close monitoring and aggressive treatment will be significant. For most other patients, accurate assessment of control is more important than severity assignment in order to adequately manage asthma.

Asthma control is divided into two components: impairment or symptom control and risk. The *impairment* domain refers to daytime and nighttime symptoms (i.e., cough, wheeze, exercise limitation), the need for rescue medication (SABA) for the treatment of symptoms, deviation from normal levels of activity (i.e., playing, sleeping, attending work or school), preserving normal or near-normal lung function, and meeting patient and parent expectations. The *risk* domain refers to preventing severe exacerbations that require medical attention, such as prescription of systemic steroids, emergency medical treatment or hospitalization, loss of lung function or impairment of normal lung growth, and adverse effects caused by medication use. This strategy draws attention to the management of current symptoms and functional impairment, as well as the future effects of asthma and its treatment on lung function and severe exacerbations. It also highlights the very important observation that asthma treatment strategies that improve symptoms may not always result in the prevention of significant exacerbations.

Asthma is best managed in a continuous fashion by forming a partnership with a knowledgeable physician or other health care provider. The concept of expecting a near symptom-free lifestyle (for all but the most severely affected patients) should be instilled in patients and their families. Unnecessary restrictions of the child's and family's lifestyles should be avoided. Participation in recreational activities, sports, and school attendance should all be expected. Psychosocial factors such as the child's behavior, social adjustments in the family and at school, and attitudes toward managing asthma should also be addressed. Parents should understand that asthma is a chronic disease with acute exacerbations that with currently available treatments can be controlled, but not cured. As better characterization of the inflammatory processes and pathways that affect the airway in specific patients and development of real-time noninvasive monitoring techniques occurs, more precise control of asthma symptoms or even primary or secondary disease prevention may become a realistic goal of asthma management.

## Classification of Asthma

Over the past decade, increasing awareness has been focused on the broad heterogeneity of asthma, both with respect to its causes, manifestations, and response to treatment. Identification of specific asthma phenotypes is expanding, and the use of biomarkers, molecular phenotyping, and cluster analysis based on symptoms, lung function, and comorbidities can help identify specific subtypes. Age of onset of symptoms, lung function, inflammatory cell types and mediators in induced sputum, and atopic versus nonatopic are all markers used to characterize disease severity, symptom pattern, and response to treatment. Considerable research is still needed to accurately identify asthma phenotypes and to determine clinically useful methods for classification.

Although the clinical utility is somewhat questionable, asthma severity refers to the intrinsic intensity of the disease and may be classified into broad categories based on frequency of daytime and nighttime symptoms, play or activity limitation, need for rescue/reliever treatment, and objective measures of pulmonary function (PEFR or FEV$_1$) that are typically present *before* the patient is treated. In addition, the number, frequency, and intensity of severe exacerbations—defined as an increase in symptoms sufficient to warrant treatment with oral corticosteroids or treatment in the emergency department or inpatient hospital unit—are considered. Some patients who have relatively well-controlled symptoms and good functional status may have frequent or intense exacerbations. Although the correlation between the number and intensity of exacerbations with severity levels is less clear, the greater the number and severity (e.g., need for hospitalization, intensive care treatment), the higher the severity. However, the degree of severity of asthma often changes in a given individual with time, response to treatment, airway injury or growth, the development of newly acquired allergic sensitivities, or change in exposure to recognized triggers. As a result, determination of *control* after treatment has been instituted is of greater significance than assigning a severity level. Using very similar criteria, asthma is determined to be well controlled, not well controlled, or very poorly controlled (Table 45.3). Control is determined at every visit, and appropriate treatment adjustments are made. The frequency of physician office visits for assessment of asthma control is variable and depends on disease activity but typically is every 1–6 months. Those with poor control or recent exacerbation may require more frequent visits for treatment monitoring of response and adjustment and monitoring of lung function. Since asthma is a chronic disorder that may become clinically obvious only periodically—one in which the severity of airway obstruction, intensity of symptoms, and degree of impairment is frequently underestimated by physicians and patients alike, the use of a standard, validated questionnaire can help overcome this discrepancy.

## Table 45.3

## Assessing Asthma Control and Adjusting Therapy in Children 5–12 Years of Age

| **Components of Control** | **CLASSIFICATION OF ASTHMA CONTROL (5–11 YEARS OF AGE)** | | | |
|---|---|---|---|---|
| | | **Well Controlled** | **Not Well Controlled** | **Very Poorly Controlled** |
| Impairment | Symptoms | ≤2 days/week but | >2 days/week or | Throughout the |

| | | | | |
|---|---|---|---|---|
| | | not more than once on each day. | multiple time on less than 2 days/week | day |
| | Nighttime awakenings | ≤1×/month | ≥2×/month | ≥2×/week |
| | Interference with normal activity | None | Some limitation | Extremely limited |
| | Short acting beta-agonist use for symptom control (not prevention of EIB) | ≤2 days/week | >2 days/week | Several times per day |
| | Lung function | | | |
| | $FEV_1$ or peak flow | >80% predicted/personal best | 60%–80% predicted/personal best | <60% predicted/personal best |
| | $FEV_1/FVC$ | >80% | 75%–80% | <75% |
| Risk | Exacerbations requiring oral systemic corticosteroids | 0–1/year | ≥2/year (see note) | |
| | | **CONSIDER SEVERITY AND INTERVAL SINCE LAST EXACERBATION** | | |
| | Reduction in lung growth | Evaluation requires long-term follow-up | | |
| | Treatment related adverse effects | Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk. | | |
| | Recommended action for treatment (See Fig. 45.1B for treatment steps) | Maintain current step<br>Regular follow-up every 1–6 months<br>Consider step down if well controlled for at least 3 months | Step up at least 1 step and<br>Reevaluate in 2–6 weeks<br>For side effects consider alternative treatment options | Consider short course of oral systemic corticosteroids<br>Step up at least 1 step and<br>Reevaluate in 2–6 weeks<br>For side effects consider alternative treatment options |

The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.

The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks and by spirometry/or peak flow measures. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient's asthma is better or worse since the last visit.

At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

Before step up in therapy:

Review adherence to medications, inhaler technique, environmental control, and comorbid conditions.

If alternative treatment option was used in step, discontinue it and use preferred treatment for that step.

*EIB*, Exercise-induced bronchospasm; *$FEV_1$*, forced expiratory volume in 1 second; *FVC*, forced vital capacity.

From NIH Expert Panel Report 3.[1]

There are several short, self-administered instruments (e.g., the Asthma Control Test [ACT], Asthma Control Questionnaire, Asthma Therapy Assessment Questionnaire) that provide a score indicative of well-controlled, not well-controlled, and poorly controlled asthma.[1] These tools do not assess the risk domain, which must also be factored into treatment decisions. A newer measure, the Composite Asthma Severity Index (CASI), incorporates symptoms, treatment level, exacerbations, and lung function into a measure that shows better responsiveness than the ACT or symptom measure alone.[73] Further validation will be necessary to determine its clinical utility.

The most recent NHLBI guidelines classify asthma as either *intermittent* or *persistent* and within the persistent category as *mild, moderate,* or *severe.*[1,74,75]

The use of cluster analysis techniques shows promise in further stratifying severe asthma phenotypes into more discrete subtypes that will help with prospective identification and long-term follow-up and treatment.[76] See Chapter 46 for a detailed discussion of severe asthma.

## Other Measures for Assessing Asthma Severity and Control

Biomarkers that provide more information on disease activity and severity could better guide asthma treatment and improve control or reduce exacerbations. However, currently available tests are limited in both availability and utility or practicality. Older models using degree of airway reactivity based on methacholine responsiveness or proportion of eosinophils contained in induced sputum, and then adjusting treatment to decrease airway reactivity or eosinophil counts were shown to achieve better pulmonary function and fewer exacerbations than monitoring symptoms and pulmonary function alone in adults.[1] However, repeated methacholine challenge testing or sputum induction is expensive, time-consuming, and generally impractical in the clinical setting, especially in the pediatric population. As discussed earlier, FeNO has been proposed as an easily obtainable measure of eosinophilic airway inflammation and could therefore be used to titrate treatment to achieve better control. Although in steroid-naïve asthmatics FeNO is elevated and in most patients the levels decrease within 1 week of instituting inhaled steroid treatment, FeNO remains essentially unchanged in as many as 30%, even when clinical improvement occurs.[59] Moreover, a number of large randomized, controlled trials that used either daily home or intermittent in-office FeNO measures to adjust treatment failed to find a difference in improvement in the number of symptom-free days or a reduction in ICS dose when compared with standard treatment using symptom report and pulmonary function measures.[77,78] It has been suggested that FeNO may be useful when there is discordance between patient-reported symptoms and airway inflammation.[63] However, data from one prospective study using ACT and FeNO to monitor asthma control and adjust treatment in school-aged children did not support added benefit from FeNO measurement.[79] In addition, nearly a third of the patients switched from a concordant to discordant phenotype over the course of 4 weeks in the trial. Although symptom-free days improved over a year in those with unstable phenotype, there was no difference in those in the FeNO group compared with those without FeNO monitoring. In spite of its limitations, FeNO may be useful in some settings, such as a diagnostic aid for asthma, identification of steroid-responsive patients, and (to a lesser extent) adjusting the dose of controller medications and predicting relapse during medication taper.

Recently there has been substantial interest in the airway microbiome, with several lines of evidence supporting a role for the bacterial ecosystem of the upper and lower airway in both maintaining pulmonary health and causing chronic conditions, such as asthma. Although there are data that suggest the airway microbiome may differ in those with asthma and healthy controls, as well as differences between degrees of asthma severity,[80,81] further research is needed to determine causation and influences of microbiome on immune dysregulation in the airways. Moreover, it is likely that there are "fungal-biomes" and "viral-biomes" that may also influence development and severity of airway disorders, but little data are currently available.

# Pharmacologic Management of Asthma in Children Older Than 5 Years of Age

The medical treatment of asthma involves the administration of controller medications designed to prevent asthma symptoms and the use of rapid-acting reliever medications that quickly abort acute exacerbations. Controller medications are administered to all asthmatics other than those with intermittent disease and are typically, but not uniformly, antiinflammatory in nature (Table 45.4A). Reliever medications are SABA or anticholinergics. Several immunomodulatory drugs are currently available for treatment of severe persistent asthma and a number of other such biologics are under development, discussed in Chapter 48.

**Table 45.4A**

**Usual Dosages for Long-Term Controller Medications**

| Medication | Youth >12 Years | Child Dose |
|---|---|---|
| **SYSTEMIC CORTICOSTEROIDS** | | |
| Methylprednisolone (chronic control) | 7.5–60 mg<br>Once daily or every other day as needed for control | 0.25–2 mg/kg[1] |
| Prednisolone, prednisone (short-course for exacerbation) | 40–60 mg<br>Administer for 3–10 days once or in 2 divided doses | 1–2 mg/kg maximum 60 mg/day |
| Dexamethasone | 10–16 mg | 0.6 mg/kg, |

|  |  |  |
|---|---|---|
|  | Give oral or IM for 1–2 days | maximum 16 mg |
| **LONG-ACTING INHALED β-2 AGONISTS**[a] |  |  |
| Salmeterol 50 µg/puff | 50 µg q 12 h | 50 µg q 12 h |
| Formoterol 12 µg/capsule | 1 capsule q 12 h | 1 capsule q 12 h |
| **COMBINATION MEDICATION** |  |  |
| **Fluticasone/Salmeterol** |  |  |
| DPI 100, 250, 500 µg/50 µg | 1 inhalation bid | 1 inhalation bid |
| MDI 45/21, 115/21, 230/21 µg | 2 inhalations bid | 1–2 inhalations bid |
| Budesonide/formoterol MDI 80/4.5; 160/4.5 µg | 1–2 inhalations bid | 1–2 inhalations bid |
| Mometasone/formoterol MDI 100/5 µg; 200/5 µg | 1–2 inhalations bid<br>Adjust dose strength to achieve control | 1–2 inhalations bid |
| **LEUKOTRIENE MODIFIERS** |  |  |
| Montelukast | 5 mg daily (6–14 years)<br>10 mg daily (>14 years) | 4 mg daily (2–5 years)<br>5 mg daily (6–14 years) |
| Zafirlukast | 20 mg twice daily | 10 mg twice daily (7–11 years) |
| Zileuton | 1200 mg bid |  |
| **Methylxanthines** |  |  |
| Theophylline, sustained release | 300 mg daily<br>Adjust dose to serum concentration 5–10 mg/mL | 10/mg/kg daily, max 300 mg |

[a] Should not be used for symptom relief or for exacerbations. Use with inhaled corticosteroids.

*DPI*, Dry-powder inhaler; *IM*, intramuscular; *MDI*, metered-dose inhaler.

## Reliever Medications: Short-Acting β Agonists

Short acting $\beta_2$-adrenergic agonists (SABAs) constitute the most potent bronchodilators currently available for treatment of asthma[1] and are used to relieve bronchospasm and its attendant symptoms of cough, wheezing, and shortness of breath. SABAs bind to the widely distributed BAR (primarily those located on the bronchial smooth muscle, airway epithelial cell, and mast cell) and result in the intracellular conversion of adenosine triphosphate (ATP) to adenosine 3′, 5′ cyclic monophosphate. The result is relaxation of airway smooth muscle and improved air flow. Onset of action is generally within a few minutes, peak action occurs at approximately 30 minutes, and duration of action is from 4 to 6 hours.[1] The preferred route of administration is by inhalation, because this method results in the most rapid onset and duration of action while minimizing adverse effects. Inhalation of SABAs can be accomplished with the use of a small-volume jet nebulizer, metered-dose inhaler (MDI; usually and ideally with a spacer), or dry-powder inhaler (DPI).

Several selective SABAs are available for treating acute asthma, such as terbutaline and albuterol. Racemic albuterol, the predominant bronchodilator in current use, is a 50 : 50 mixture of (R)-enantiomers and (S)-enantiomers. Levalbuterol, the (R)-albuterol isomer, has a 100-fold more potent $\beta_2$ receptor binding than (S)-albuterol, and it is responsible for the bronchodilator effects of the racemate. In vitro, (S)-albuterol has been demonstrated to increase intracellular $Ca^{2+}$ to stimulate eosinophil recruitment and degranulation and recruit other inflammatory cells. The in vivo effects of (S)-albuterol remain unproven; however, it has no bronchodilator activity and has a prolonged plasma half-life, but it does not cause bronchoconstriction or interfere with the binding of (R)-albuterol to its receptor. When administered in equivalent doses based on the concentration of (R)-albuterol, there does not appear to be any consistent clinical advantage to using levalbuterol versus racemic albuterol as measured by improvement in clinical symptoms, pulmonary function testing, or adverse effect profile. Since levalbuterol is typically more expensive than the racemic drug, the routine use of levalbuterol is generally not recommended.

Typical adverse effects of SABAs include muscular tremor, tachycardia, irritability, and with very high doses, hypokalemia, hypertension, and tachyarrhythmia. Adverse effects are greater with systemic administration (oral, intravenous [IV], intramuscular [IM]) compared with the inhaled route. Moreover, the dose delivered by an MDI is substantially less than that from a small-volume nebulizer, and since most of the inhaled dose is swallowed and absorbed by the gastrointestinal tract, annoying side effects are best minimized by using an MDI with an appropriate spacer.

The clinical significance of serious adverse events that develop as a result of the chronic administration of inhaled SABAs is, in most instances, probably less than was once believed. The current recommendation is for the as-needed use of a SABA for relief of symptoms or for protection against EIA. A retrospective review of prescription records in patients in Canada found an increased risk for asthma death or near-death in patients who used more than one canister of a SABA per month. However, an association with the use of a number of other asthma medications was also noted, suggesting that disease severity might actually be more causative than overuse of SABAs alone.[82] Nonetheless, SABA overuse is a worrying marker of future risk.

Reports have suggested that repeated use of a SABA may result in an increase in airway hyperresponsiveness or a decrease in protection from allergen-induced bronchospasm. The reduction in beneficial effects of SABA following chronic use may result in part from receptor desensitization, uncoupling of the receptor from its signaling G protein, inactivation of receptors, or reduction in receptor number caused by increased degradation or decreased synthesis. A well-designed randomized double-blind placebo-controlled study performed in adults with mild asthma examined the effects of regularly administered albuterol versus intermittent administration compared with placebo. There was no significant difference in any outcome measures between the groups, including exacerbations, treatment failures, lung function, symptoms, or methacholine responsiveness.[83] However, regular use of albuterol was also not beneficial to the patients. Finally, there may be specific subgroups of patients who are at risk for developing adverse effects, as measured by worsening pulmonary function with chronic use of SABAs, and this may be related to genetic variability in the BAR. Nine polymorphisms in the *BAR* gene have been described, and several of the more frequent types may have biological significance. One involves the beta 2AR-16 region, with replacement of arginine (Arg16) for glycine (Gly16). In a study involving bronchodilator response in children, those with the *Arg/Arg* polymorphism had the highest prevalence (60%) of bronchodilator response to a single dose of albuterol, whereas fewer than 30% of those with the *Arg/Gly* polymorphism responded and only 13% of those with the *Gly/Gly* polymorphism were responders.[84] In contrast, data from a prospective study of chronic albuterol administration to patients segregated by BAR genotype found that those with the Arg16 homozygous polymorphism had steadily declining PEFR as compared with those receiving intermittent treatment or treatment with ipratropium.[85] This effect did not occur in those with the *Gly/Gly* genotype. Chronic administration of ipratropium to the *Arg/Arg* group did not result in PEFR deterioration. In addition, recent studies point to other polymorphisms not associated with the BAR but related to smooth muscle proliferation that are associated with differential responsiveness to short acting beta-agonists.[86–88] Lastly, rare genetic variants that are associated with ethnicity are also likely contributors to the variability in response to SABA. A study in Latino children described a number of such rare genetic variants in genes associated with membrane ion transport, vascular smooth muscle adhesion, and TGF-beta pathways.[89] These data indicate the importance of understanding ethnic and ancestral background in identifying genetic risks for SABA responsiveness.

## Anticholinergic Agents

Ipratropium bromide is a quaternary ammonium congener of atropine and is an anticholinergic compound approved for use as a bronchodilator. Anticholinergic agents produce bronchodilatation by antagonizing the activity of acetylcholine at the level of its receptor, particularly those found on airway smooth muscle in the large, central airways. The onset of action of ipratropium is relatively slow (20 minutes), and the peak effect occurs at 60 minutes.[1] Ipratropium, unlike atropine, is poorly absorbed across mucous membranes and has little toxicity at the usual doses. In particular, ipratropium does not inhibit mucociliary clearance. Data from several studies conducted in children presenting to the emergency department for treatment of acute asthma indicate that when combined with a β-adrenergic agonist, ipratropium improves pulmonary function and relieves symptoms better than either drug alone.[1] The effect is modest and appears to be most evident in those who present with the most severe airway obstruction; this may be a marker for patients who have increased cholinergic tone in the large central airways. Ipratropium has not been shown to be effective in the treatment of children hospitalized with acute asthma, particularly if ipratropium failed to induce improvement when administered in the emergency department.[90]

# Controller Medications

## Inhaled Corticosteroids

ICSs are currently considered the most effective controller medication available for the treatment of chronic asthma. Most ICSs have a high topical potency and relatively low systemic effects, either as a result of poor absorption or rapid and effective metabolism to inactive compounds. However, all ICSs are absorbed through the respiratory epithelium to some degree, resulting in the potential for systemic effects.

The ideal ICS should demonstrate excellent clinical efficacy and minimal to no toxicity in combination with a convenient and easy-to-use inhaler device. To achieve such a profile, an ICS should have the following properties: a high affinity for and potency at the glucocorticoid receptor (GR); prolonged retention in the lung; a high level of serum protein binding for the systemically absorbed fraction; a high volume of distribution; minimal or no oral bioavailability; and rapid, complete systemic inactivation (e.g., high first-pass hepatic inactivation, or inactivation in the lung before systemic absorption).[91] Together these properties confer a higher therapeutic index with prolonged antiinflammatory activity in the lung and relatively few systemic adverse effects. Pharmacologic properties alone are not sufficient for optimum clinical effect. The delivery devices should provide maximal deposition in the lung in both large and smaller airways, with little to no deposition or absorption in the oropharynx or gastrointestinal tract. Once-daily administration is also likely to improve patient adherence. Inhalation devices should be simple to use, should be acceptable to a wide age range, and should deliver a consistent dose throughout the life of the inhaler.

## Fluticasone Propionate

Fluticasone propionate (FP) is a potent and poorly orally absorbed topically active corticosteroid that is extensively metabolized in the liver to an inactive compound. This highly lipophilic drug demonstrates an extremely high affinity for lung GRs compared with beclomethasone (BDP) and shows a slow rate of dissociation from its receptor. As a result, FP has a negligible oral bioavailability, and the topical-to-systemic activity ratio is exceptionally favorable and better than most currently available ICSs. However, FP is readily absorbed through the respiratory mucosa and can enter the systemic circulation in this fashion (without hepatic metabolism). FP is more likely to produce sore throat and hoarseness than other ICS. In addition, there have been reports of adrenal suppression in children younger than 12 years of age who receive more than 400 μg/day of FP, but the data are inconsistent. FP is therefore considered a high-potency ICS, with the potential to effectively control symptoms and improve lung function, but at higher doses it has greater potential to cause adverse effects. In vivo, FP appears at least twice as potent as BDP and BUD on a milligram-per-milligram basis. Comparative trials indicate that fluticasone at half the dose of BUD and BDP results in a slight improvement of some pulmonary function measures, such as morning PEFR and end-of-treatment trial $FEV_1$.[92] FP is currently available in MDI and DPI form in three strengths (Table 45.5); it is approved in the United States for use in children 4 years of age and older.

## Table 45.5

## Estimated Comparative Daily Dosages for Inhaled Corticosteroid in Older Children and Adults

| Drug | Low Daily Dose | | Medium Daily Dose | | High Daily Dose | |
|---|---|---|---|---|---|---|
| | 5–11 years | >12 years | 5–11 years | >12 years | 5–11 years | >12 years |
| Beclomethasone HFA 40 or 80 μg/puff | 80–160 μg | 80–240 μg | >160–320 μg | >240–480 μg | >320 μg | >480 μg |
| Budesonide suspension for nebulization dry powder (90, 180, or 200 μg/inhalation) | 0.5 mg<br>180–400 μg | 180–600 μg | 1.0 mg<br>400–800 μg | >600–1200 μg | >2.0 mg<br>>800 μg | >1200 μg |
| Flunisolide HFA 80 μg/puff | 160 μg | 320 μg | 320 μg | 320–640 μg | ≥ 640 μg | >640 μg |
| Fluticasone dipropionate | 88– | 88– | >176– | 264– | >352 | >440 |

| | | | | | | |
|---|---|---|---|---|---|---|
| HFA/MDI: 44, 110, 220 µg/puff<br>DPI: 50, 100, 250 µg/puff | 176 µg<br>100–200 µg | 264 µg<br>100–300 µg | 352 µg<br>200–400 µg | 440 µg<br>300–500 µg | µg<br>>400 µg | µg<br>>500 µg |
| Fluticasone furoate 100, 200 µg/puff | NA | 100 µg/day | NA | 200 µg/day | NA | 400 µg/day |
| Mometasone DPI 110, 220 µg/puff | 110 µg | 220 µg | 110–220 mcg | 440 µg | >440 µg | >880 µg |
| Ciclesonide MDI 80, 160 µg/puff | NA | 160 µg | NA | 320 µg | NA | 640 µg |

*DPI*, Dry-powder inhaler; *HFA*, Hydrofluoroalkane; *NA*, not approved for this age group; *MDI*, metered-dose inhaler.

Adapted from NAEPP Expert Report 3.[1]

Fluticasone furoate is a new formulation of fluticasone that has an extended half-life and can be taken once daily. It is available in the United States as a dry powder inhaler in doses of 100 µg or 200 µg of fluticasone administered once per day and approved for children and adolescents 12 years of age and older. The dose response curve is similar to other ICS formulations.[93] Fluticasone furoate is also available with a fixed dose of 25 µg of the long-acting beta-agonist, vilanterol per inhalation. At the current time, the combination inhaler has been approved for use only in adults with COPD and asthma.

## Budesonide

BUD has been widely studied and used clinically for many years. It has moderate potency in vitro and in vivo, with well-documented clinical efficacy and safety. In addition, the presence of a free C21 hydroxy group on the BUD molecule results in formation of esters with long-chain fatty acids. This results in an inactive depot of drug within the airway epithelial cells that is released slowly into an active state. BUD is currently available in a dry powder inhaler and a nebulizer suspension. BUD is approved in the United States for use in children 1 year of age and older. It is available in combination with formoterol in an MDI form, which is approved in the United States for use in children age ≥12 years.

## Beclomethasone

Although clearly less potent than FP and slightly less so than BUD, BDP is effective in reducing symptoms and improving pulmonary function. However, BDP is readily absorbed from the gastrointestinal tract, and the parent compound (BDP) is metabolized to the more potent monopropionate. As a result, BDP has a less favorable topical-to-systemic potency ratio. However, concerns about its ability to cause adverse effects such as growth and adrenal suppression have not been substantiated. BDP is currently available as a fine-particle aerosol dispensed by a hydrofluoroalkane propellant. This propellant system permits greater deposition into the lower and smaller airways and a reduction in the effective dose. The clinical advantage of these properties remains to be clarified. BDP is approved in the United States for use in children 5 years of age and older. In low- and middle-income countries, the low cost of BDP makes it a very attractive medication.

## Mometasone

Mometasone is a potent, highly topically active steroid that has long been used to treat allergic rhinitis and dermatologic disorders. It has the advantage of poor systemic absorption and has been shown to be effective in improving lung function and controlling symptoms in children with asthma who were previously treated with other ICSs and SABAs. Mometasone is similar to FP in its high receptor affinity and half-life. It appears to have a similar safety profile to other ICSs. Mometasone is approved in the United States for use in children 4 years of age and older. It is available in both DPI and MDI forms for treatment of asthma and is labeled for once-a-day dosing.

## Ciclesonide

Ciclesonide is a prodrug that must be metabolized to active form in the lung, where its metabolite has approximately 100 times greater receptor affinity. It has essentially no oral bioavailability and is tightly bound to plasma proteins. Ciclesonide is converted at the airway epithelial cell into its active metabolite, des-ciclesonide (Des-CIC); the enzyme responsible for the conversion is only found in the lower respiratory tract. A recent meta-analysis concluded that ciclesonide was probably as effective as fluticasone, BUD, and BDP in equivalent doses at improving pulmonary function and controlling mild symptoms. Incidence of oral candidiasis was lower in groups treated with ciclesonide. A single long-term (12-month) safety study in children compared two doses of ciclesonide to placebo and concluded that there was no significant effect on linear growth or adrenal suppression.[94] The study was somewhat flawed in that there was no active comparator, no clinical effect of drug was seen, and adherence was indirectly measured. Further studies in children are necessary to assess dose responsiveness and safety. Ciclesonide is approved in the United States for use in children 12 years of age and older.

# Other Inhaled Corticosteroids

Flunisolide is an older, relatively less potent steroid that, while effective, is less commonly used. It must be given in fairly high microgram amounts, resulting in a bitter unpleasant taste.

## Mechanism of Action and Clinical Use

There are several pathways through which corticosteroids decrease inflammation. The action of corticosteroids begins as passive diffusion across the cell membrane and into the cytoplasm where binding to the GR occurs. The GR exists in the cytoplasm as a large heterodimeric complex that includes two 90-kD heat shock protein (HSP) molecules. After hormone binding, the HSPs are shed, the receptor-steroid complex is translocated to the nucleus, and then binds as a dimer to a glucocorticoid response element (GRE) on steroid-responsive genes. The GR acts to regulate transcription of target genes either directly or indirectly by interaction with other transcription factors. The binding of the GR complex to GRE results in either induction or repression of a gene. The number of GREs and the proximity to transcriptional start sites affects the steroid inducibility of the gene. Activation of inflammatory genes is achieved by histone acetylation of the transcription complex. At low doses, steroids suppress inflammation by recruiting histone deacetylase-2 (HDAC2) to inactivate transcription of these genes.

GRs may also act independently of binding to GRE by coactivating other transcription factors (e.g., STAT5). At higher doses, glucocorticoids control inflammation by increasing histone acetylation of the transcription complex of antiinflammatory genes.[95]

A major mediator of corticosteroid action on genes is the nuclear transcription factor NFκB (nuclear factor kappa-light-chain-enhancer of activated B cells). Corticosteroids block NFκB signaling by preventing it from binding to DNA, which decreases transcription of proinflammatory cytokines. Corticosteroids may also inhibit NFκB by directly increasing production of its cytoplasmic inhibitor protein IκB. IκB proteins bind to NFκB and keep it anchored in the cytoplasm. In this manner, corticosteroids inhibit the transcription of a number of cytokines and chemokines implicated in the pathogenesis of asthma, such as interleukin-1 (IL-1) through IL-6, tumor necrosis factor alpha (TNF$\alpha$), granulocyte-macrophage colony-stimulating factor, IL-13, IL-8, released on activation, normal T cell expressed and secreted (RANTES), and eotaxin. Steroids may also inhibit the synthesis of some cytokine receptors, such as the IL-4 receptor, intracellular adhesion molecule (ICAM), and vascular cell adhesion molecule (VCAM). In addition to the action on cytokines, steroids also inhibit the inducible form of NO synthase, cyclooxygenase, phospholipase A2, and endothelin, all important factors in the inflammatory cascade relevant to asthma. Corticosteroids also increase the synthesis of BAR by increasing gene transcription.[75,95]

Because topical steroids can also cause rapid effects (e.g., skin blanching), it is likely that there is also a rapid cellular mechanism of action with transient vasoconstriction in the microcirculation, which is independent of the genomic mechanism.[96] This action could involve the generation of vasoconstrictive mediators either at the point of gluco-corticoid (GC) binding to certain membrane receptors or at the time of dissociation of the HSP from the cytoplasmic receptor complex.

ICSs are currently recommended as first-line therapy for children with persistent asthma. ICSs are the most effective chronic treatment for asthma and reduce airway reactivity, reduce acute symptoms and exacerbations, attenuate the late allergen response, and decrease the need for rescue bronchodilators. In addition, ICSs decrease deposition of collagen and extracellular matrix glycoproteins, or tenascins, in the subepithelial basement membrane. For these reasons, ICSs alone should be used as the initial treatment for persistent asthma; it is not appropriate, in the vast majority of cases, to use a fixed-dose combination of ICS plus a long-acting β-agonist as initial treatment. Withdrawal of ICS treatment is usually accompanied by a rapid return of airway hyperresponsiveness and decreased symptom control within several weeks.

A small but not insignificant proportion of patients do not have a significant response to ICS. Children and adolescents who are obese, smoke cigarettes, and have significant and continuous exposure to certain allergens are relatively refractory to the beneficial effects of ICSs on symptoms and lung function. The mechanisms of this relative steroid resistance are not yet fully understood. Recent data suggest that vitamin D deficiency is associated with worse asthma control, and the mechanism may involve induced steroid resistance.[97] Vitamin D deficiency is associated with increased oxidative stress and enhanced expression of inflammatory mediators such as TNF$\alpha$ and NF-κB in patients with asthma exacerbations.[98] Vitamin D also prevents the conversion of CD8 T lymphocytes to those that produce IL-13 by affecting activity of CYP11A1, a steroidogenic enzyme.[99,100] Studies to further examine the role of vitamin D in steroid resistance are ongoing. Oxidative stress also results in reduced expression and activity of HDAC2; consequently, transcription of inflammatory genes is not inactivated and inflammation becomes resistant to the antiinflammatory actions of glucocorticoids.[95]

The dose-response curve for ICS treatment reaches a plateau at a fairly low dose in most patients, and there is little added benefit to pulmonary function or airway reactivity when doses are as much as quadrupled. A study performed in adults to evaluate the efficacy and safety of escalating doses of ICS demonstrated that, for the majority of patients, maximal improvement in $FEV_1$ and methacholine responsiveness occurred at low to moderate doses of FP and BDP, with no added benefit of extremely high doses.[101] However, a substantial linear increase in cortisol suppression was seen as ICS dose increased. Therefore in the majority of patients, the most clinical benefit with the least risk will occur at low to medium doses of ICS. However, higher doses of ICS may be required to effectively decrease serious exacerbations. Patients receiving higher ICS doses require more careful monitoring for both response to therapy and emergence of systemic side effects.

## Adverse Effects of Inhaled Corticosteroids

Local adverse effects, such as oral candidiasis and dysphonia, are the most common but least severe complications of ICS treatment. They are dose-related with some variability depending on steroid type, and they only occur in a small minority of patients (1%–3%). Reducing the dose, using a spacer device, and rinsing the mouth with water after use may minimize both these side effects. The more serious systemic adverse effects for children include adrenal suppression and depression of linear growth. A meta-analysis of 15 studies comparing low to medium dose ICS with placebo or nonsteroidal drugs in a total of more than 5700 children for at least 3 months found a mean reduction in linear growth velocity of 0.48 cm per year and a decrease of 0.6 cm from predicted height over 12 months in children who received ICS. There were no differences in growth velocity between placebo and ICS groups over subsequent years in the few studies that reported growth for longer than 1 year.[102] Thus the effect of ICSs on linear growth in most patients is minimal, even after long-term administration of low-dose ICSs. Most of the decrease in growth velocity appears in the first few months after initiating steroid treatment. The specific ICS molecule given was more important than age, delivery device, or dose in determining the magnitude of the effect.[102–104] However, head-to-head comparisons among ICS molecules are needed to provide more definitive data. Data on the growth of children in the 4-year-long CAMP trial demonstrated that there was indeed a significant decline in growth velocity over the first year of the study, but the growth rate returned to normal thereafter. Children in the BUD group were on average 1.1 cm shorter than those in the placebo and nedocromil groups at the end of the 4-year treatment period.[16] In addition, Agertoft and Pedersen showed that there was no reduction in final predicted adult height in a group of 142 children treated with a mean dose of 400 μg/day of BUD for an average of 9.2 years.[105] These longer-term studies of chronic low-dose ICSs point to an excellent safety profile and the potential to reach final predicted adult height, in spite of short-term decline in height velocity.

Adrenal suppression has been extensively studied, although the results are often difficult to interpret owing to flawed design, previous use of oral corticosteroids, or inappropriate tests used to assess adrenal function. Nonetheless, adrenal suppression is unlikely in children receiving less than 400 μg/day of inhaled BUD, or fluticasone 200 μg/day, even after long-term use.[1,16]

Adrenal suppression indicated by impaired adrenocorticotropic hormone stimulation tests can be demonstrated in children receiving higher doses; however, in most patients, even these impairments are of no or uncertain clinical significance when the patient is well. A significant stress (e.g., major illness, surgery) could warrant administration of exogenous corticosteroids to prevent an Addisonian response.[106]

Since there is variability among individual clinical response to corticosteroids and the predisposition to develop adverse effects, careful monitoring of each patient's growth during ICS treatment should be performed, and the dose should be adjusted to the lowest necessary to achieve good symptom control.

## Systemic Corticosteroids

The therapeutic benefits of systemic corticosteroids when used as chronic therapy are marred by their potential adverse effects, which include excessive weight gain, hypertension, osteoporosis, decreased linear growth, metabolic derangement, and cataracts. Adverse effects from long-term steroid therapy may be reduced, but not eliminated, by using steroids with shorter half-lives (e.g., prednisone, prednisolone, methylprednisolone) at the lowest possible dose administered in the morning in a single dose and given every other day.

## Long-Acting β Agonists

β-adrenergic agonists that have a prolonged duration of action (8–24 hours) occupy a unique niche in the asthma treatment armamentarium, somewhere between that of a controller and a reliever medication. There are currently two long-acting β agonists (LABAs) available on the US market and approved for use in children: salmeterol (approved for patients 4 years of age and older) and formoterol (approved for patients 12 years of age and older); others, such as indacaterol and vilanterol, both ultralong acting $\beta_2$ agonists with a 24-hour duration of action, are available but not approved for use in children. Indacaterol is approved only for treatment of COPD, and vilanterol is only approved to treat *adults* with asthma.

Formoterol and salmeterol differ in structure, potency, efficacy, and selectivity for the beta receptor. Salmeterol is a partial agonist, has a relatively slow onset of action (10–30 minutes), and has extremely high selectivity for the $\beta_2$ receptor. Salmeterol is more than 10,000 times more lipophilic than albuterol, and it also has three to four times the affinity for the $\beta_2$ receptor of albuterol. However, salmeterol diffuses out into the cell membrane somewhat slowly to approach the $\beta_2$ adrenoceptor active site, which results in a slower onset of action. Salmeterol has a long side chain that interacts with an exosite domain of the $\beta_2$ receptor. This side chain attachment allows association and dissociation with the active receptor site for a prolonged time period and results in the long duration of drug action (9–12 hours).[107,108] Salmeterol is available as both a dry powder in a Diskus device and in combination with fluticasone as a MDI in the United States.

Formoterol is a moderately lipophilic, highly effective full agonist with a very different molecular structure from salmeterol. It is taken up into the cell membrane to form a dose-dependent depot, from where it progressively diffuses out to interact with the active site. It has a rapid onset of action (~5 minutes) comparable to albuterol, but duration of activity is 12 hours. Formoterol is dispensed as a DPI or MDI in the United States and is also available in combination with BUD or mometasone in the United States.

The continued use of LABAs can lead to an alteration in their biologic effects. Although the mechanisms of tolerance to the bronchoprotective effect are unclear, downregulation of beta-receptor number or lack of receptor sensitivity are possibilities. Following a single dose of salmeterol (25–50 μg), there is sustained improvement in bronchodilatation for at least 12 hours, as well as a bronchoprotective effect to the bronchoconstriction caused by both methacholine and exercise. However, after repeated doses, within a few days or weeks there is a loss in the degree of bronchoprotection to methacholine and exercise. However, the loss of bronchoprotection is greater for exercise than in the response to methacholine, but it is unclear if this is clinically significant. When used as monotherapy (which is medical negligence in children), protection from EIB persists after daily dosing for 2–4 weeks, but in several studies the duration of action decreases from 9 to 12 hours to as little as 1 hour. The bronchodilator effect is less likely to decrease than the bronchoprotective effect following repeated dosing, and the decline is usually most apparent after a few days of use, followed by stabilization. Formoterol is likely to behave in a fashion similar to salmeterol.[108] Long-term use of LABAs has been shown to decrease responsiveness to SABA via $\beta_2$ adrenoreceptor downregulation. Similar to the decrease in bronchoprotection, the clinical significance of the reduction in response to albuterol after continued use of LABAs is unclear.[109–112] At least one study has demonstrated no loss of asthma control in patients using LABAs, even when a decrease in bronchoprotection is confirmed.[113]

The LABAs are not generally considered antiinflammatory agents, but studies show that salmeterol has either no effect on airway inflammation or reduces inflammatory cells in the airway mucosa. It has also been proposed that LABAs may enhance the actions of ICSs, and the mechanism has been linked to regulator of G-protein signaling 2 (RGS2) expression, which inhibits the intracellular influx of $Ca^{2+}$ triggered by spasmogens.[114]

Past and recent concerns persist about the use of LABAs as monotherapy and the risk of adverse events. A study performed by the Asthma Clinical Research Network demonstrated that the combination of triamcinolone and salmeterol was effective in controlling asthma in patients 12–65 years of age.[115] However, complete withdrawal of the ICS and continuation of the LABA caused significant deterioration in asthma control, as measured by asthma exacerbations, deterioration in pulmonary function, and the need for oral corticosteroid treatment. These data and those from similar studies all suggest that LABAs cannot be used as a replacement for ICSs and should never be used as monotherapy for treatment of chronic asthma. Deaths have also been reported in patients chronically using inhaled salmeterol. It remains uncertain if there is a direct link between medication use and death, or if the increase in deaths is a reflection of inappropriate use of a LABA (e.g., attempt to use it as an acute bronchodilator or in place of a controller medication). A large trial (>26,000 enrollees) compared the safety of daily salmeterol or placebo added to usual treatment for chronic asthma over a 28-week period.[116] The Salmeterol Multicenter Asthma Research Trial (SMART) trial was stopped early when an interim analysis showed futility in reaching the required enrollment numbers as well as an association between salmeterol use and severe or fatal asthma. The risk for asthma-related death, albeit small (13 of 13,174) in the salmeterol group, was significantly greater than that in the placebo group (4 of 13,179); RR = 4.37 (95%, CI 1.25–15.34) for combined asthma deaths or life-threatening experiences. This translates into a death rate of 1.98 per 1000 person-years and is significantly greater than the expected death rate in the United States asthmatic population of 0.48/1000 person-years. Importantly, the increased risk for death was stronger in African-American subjects. The African-American participants were also more likely to have more severe asthma and less likely to be treated with an ICS. However, the study was not designed or powered to accurately examine the effects of race or concomitant use of an ICS on modulating the effect of salmeterol. Although there were a number of flaws in this trial, the data resulted in a “black box” warning being placed on the salmeterol package insert advising of the potential risk of life-threatening asthma. The results of several subsequent pooled analyses of adverse effects of LABA have also supported the conclusion that unopposed LABA use is associated with asthma deaths. As a result, the US FDA now recommends that (1) LABA not be used as monotherapy, (2) LABA not be used in patients whose asthma is well-controlled on ICS alone, (3) LABA be used in combination with another controller medication, and (4) LABA be discontinued as soon as possible after asthma control is achieved. In addition, a recent meta-analysis that used reports of events provided by the drug manufacturers to the FDA suggests that there is an increased risk of death with LABA use even with the use of an ICS.[117] Reassuring results were obtained in a recent multicenter trial of 11,679 adolescents and adults where there was no increased risk for an asthma related adverse event when LABA was added to ICS therapy and delivered by a single inhaler.[118] These data remain controversial, and further large-scale trials are planned to determine the actual risk.

Some of the risk attributable to chronic LABA use may be attributed to polymorphisms in the *BAR* at the 16 position. Similar to the results obtained with chronic administration of SABA to those with the *Arg/Arg* polymorphism, it was suspected that deterioration in pulmonary function and symptom control might occur with LABA use, even when given in conjunction with an ICS. In a prospective randomized crossover 18-week study of ICS treatment plus LABA or placebo in adult patients stratified by *BAR 16* polymorphisms (*Arg/Arg* or *Gly/Gly*), there was no difference in the degree of improvement in PEFR or $FEV_1$ with the addition of LABA, regardless of genotype. However, those with the *Gly/Gly* polymorphism had a higher $PC_{20}$ with LABA treatment compared with placebo; there was no difference in $PC_{20}$ in the *Arg/Arg* group between placebo and LABA.[119] No difference in adverse effects was seen in either group. These data suggest that chronic use of LABA in combination with an ICS is safe in patients with either genotype. However, longer-duration treatment and larger-scale studies will be necessary to determine continued efficacy and safety.

A major benefit of LABAs is use in combination with an ICS to improve asthma control without increasing the steroid dose. A number of studies that included older children and adults have demonstrated that the addition of a LABA to a regimen that includes an ICS results in better asthma control and improved pulmonary function compared to doubling the dose of ICS.[120] More importantly, the ICS dose can often be reduced by as much as 50% and still maintain asthma control when the LABA is added. Although the data are striking and consistent in studies on adults, there are fewer pediatric studies. An early study suggested that addition of a LABA to an ICS in pediatric patients may not have the same steroid-sparing effect or enhancement of steroid effect as that seen in adults and found the addition of a LABA or higher-dose ICS conferred no further benefit, but growth suppression occurred at the higher ICS dose.[121] A more recent large multicenter trial (VIAPAED) compared the effect of salmeterol 50 mg plus fluticasone 100 μg combination (given in a single inhaler) compared with fluticasone 200 μg given twice daily for 8 weeks in 441 children 4–16 years of age whose asthma was not well-controlled while taking an ICS alone.[122] Children in the salmeterol plus fluticasone group had significantly greater improvement in morning PEFR (improvement of 30.4 ± 34.1 L/min combination vs. 16.7 ± 35.8 L/min fluticasone) and a longer duration of asthma control (~1 week longer, favoring combination). A meta-analysis of 10 studies examining high-dose ICS compared with low-dose ICS and LABA concluded that the addition of LABA to ICS allowed a 37%–60% reduction in inhaled steroid dose without loss of asthma control.[120]

A study conducted by the Childhood Asthma Research and Education Network in asthmatic children 6–17 years of age who were not well controlled on ICS alone examined the response to the addition of LABA, increasing the dose of ICS, or adding the leukotriene receptor antagonist (LTRA) montelukast.[123] Using a double-blind randomized triple-crossover design and a composite of three outcomes (exacerbations, asthma-control days, and $FEV_1$), this study demonstrated a differential response to the treatment steps in 161 of the 165 children enrolled. The response to LABA step-up was most likely to be the best option compared with LTRA (1.6 relative probability) or increasing the ICS dose (1.7 relative probability). White race or Hispanic ethnicity predicted a better response to LABA; African Americans were as likely to respond to LABA as to ICS step-up therapy and least likely to respond to LTRA. Although all step-up options provided good symptom control during the trial, none of the step-up options eliminated acute asthma flares. The duration of this trial was relatively short (16 weeks), and issues of safety or long-term maintenance of effect remain unanswered. Although some would argue that increasing the dose of ICS may be safer and less expensive than adding a LABA or LTRA, the more important issue is to carefully and frequently monitor the patient with poorly controlled asthma who requires any step-up therapy to ensure both safety and efficacy. Failure to improve or the development of any adverse effect or medication intolerance warrants further medication adjustment and reevaluation.

Overuse (or possibly any use) of LABA could also be detrimental to some patients, as suggested by a systematic review of adverse events associated with LABA plus ICS use.[124] However, more recent meta-analyses and systematic reviews have shown that there is no increased risk for adverse asthma-related events in patients receiving a combination of inhaled steroid and LABA compared with those receiving inhaled steroid alone in studies examining both salmeterol and formoterol.[125,126] Similar reassuring results were obtained in a recent multicenter trial of 11,679 adolescents and adults, which found there was no increased risk for asthma-related adverse events when LABA was added to ICS therapy and delivered by a single inhaler.[118] Finally, a multicenter international pediatric study including over 6200 children age 4–11 years found no increase in safety events (hospitalizations, intubation, or death) or decrease in efficacy (time to exacerbation requiring oral steroids) for fluticasone-salmeterol fixed-dose combination compared with fluticasone alone over 26 weeks.[127] There were no deaths or asthma-related intubations for any enrollees in the study regardless of treatment group; however, children with very severe or unstable asthma were not included in the study. Both of these large-scale prospective studies examining safety and efficacy of ICS and LABA provide further evidence that ICS and LABA combinations are safe for use in the pediatric population.

There are currently four fixed-dose combination-inhaled steroid and LABA medications available: fluticasone proprionate/salmeterol, BUD/formoterol, mometasone/formoterol, and fluticasone furoate/vilanterol. The dosing interval for all but one is every 12 hours (fluticasone furoate plus vilanterol is once a day). It is also possible to administer each medication separately from individual inhalers; however, this is less convenient for the patient, may be more expensive, and runs the risk of inadvertent overuse, or even sole use, of LABA. Although use of separate inhalers does allow more flexibility in adjusting the dose of ICS, this strategy is not recommended because of the risks associated with unopposed LABA use. Salmeterol is combined with fluticasone in a DPI or MDI; the dose of salmeterol is 50 μg per inhalation in the DPI and 21 μg per inhalation in the MDI, while the fluticasone component is available in three different concentrations to allow for flexibility in dosing the ICS while avoiding excessive LABA use. A combination of formoterol and BUD or mometasone is also available in DPI or MDI forms. Salmeterol is a partial agonist of the β receptor compared with formoterol, which results in a flatter dose response curve and a weaker protective effect against methacholine-induced airway reactivity for salmeterol.

When the LABA combined with an ICS is formoterol, a different dosing strategy is possible because of the rapid onset of action of formoterol. When formoterol is taken in combination with an ICS for relief of symptoms at the first sign of deterioration, the additional dose of ICS helps prevent serious exacerbation. This strategy was examined in a large multicenter trial that evaluated 2760 asthmatics 4–80 years of age who were randomized to treatment with BUD 320 mg twice daily and terbutaline as reliever, BUD/formoterol 80/4.5 mg twice daily and terbutaline as reliever, or BUD/formoterol 80/4.5 mg twice daily both as maintenance and reliever. The child treatment arm (4–11 years of age) was dosed at once a day.[128,129] Both adults and children in the BUD-formoterol as maintenance and reliever arm had significantly reduced risk of exacerbation compared to the other two treatment arms. The child study showed a significant reduction in severe exacerbations (defined as sustained fall in morning PEFR, need for oral corticosteroid, acute care visit or hospitalization); 14% of those in the combined maintenance plus reliever group had a severe exacerbation, compared with 38% in the BUD/formoterol plus SABA group and 26% in the BUD plus SABA group. In addition, the overall exposure to oral corticosteroids and exacerbations requiring medical attention was also significantly reduced in the maintenance plus reliever group. Moreover, linear growth over the year was approximately 1 cm greater in the groups receiving BUD/formoterol compared with the higher-dose BUD group.

Although this treatment approach has found acceptance in Europe, Australia, and Canada (but not in the United States), some concerns remain about safety and long-term effectiveness. Overuse of the BUD/formoterol combination can occur, leading some patients to mask progressing symptoms or delay seeking medical attention.

## Leukotriene Antagonists

Leukotrienes are lipid mediators produced by the metabolism of arachidonic acid via a complex cascade, including the action of phospholipase $A_2$. The enzyme 5-lipoxygenase catalyzes the production of leukotrienes, $LTB_4$ and the cysteinyl members $LTC_4$, $LTD_4$, and $LTE_4$, from arachidonic acid. Arachidonic acid can also be a precursor for the cyclooxygenase pathway and results in the production of prostaglandins and thromboxane. However, it is the cysteinyl leukotrienes (cysLTs) that are the potent mediators which induce smooth muscle constriction, vascular permeability, mucus hypersecretion, edema formation, and inflammatory cell recruitment into the airways. Elevated levels of cysLTs are recovered from bronchoalveolar lavage fluid, and urinary $LTE_4$ levels are elevated following airway allergen challenge in atopic asthmatics. CysLTs are produced by a number of cell types found in the airways, including mast cells, eosinophils, basophils, macrophages, and neutrophils. Corticosteroids do not directly inhibit the synthesis or block the action of leukotrienes.

Two basic strategies targeting cysLTs include inhibition of 5-lipoxygenase and leukotriene receptor antagonism. Because of the nature of the lipoxygenase synthetic cascade, interruption at an early level (e.g., at the 5-lipoxygenase) could diminish overall cysteinyl LT and $LTB_4$ production, both of which are generally elevated in biological fluids (i.e., blood, bronchoalveolar lavage fluid, urine) from symptomatic asthmatics. The 5-lipoxygenase inhibitor zileuton blocks the bronchoconstriction response to inhaled allergen or cold air challenge, exercise, and aspirin ingestion in sensitive individuals. However, because the drug can cause hepatic injury, which is usually reversible, regular liver enzyme monitoring is necessary. Although previously the drug required 4 times daily dosing, an extended release form that permits twice a day dosing is now available.

There are two clinically available LTRAs: zafirlukast and montelukast. When administered orally, zafirlukast resulted in significant reduction in daytime and nighttime symptoms and the need for SABA compared with placebo. Zafirlukast has modest efficacy at best, must be given twice daily, and in some patients also results in elevated hepatic enzymes. Montelukast is a $LTD_4$ receptor antagonist and is administered once daily. It has been shown in a number of studies to decrease urinary excretion of $LTE_4$, reduce both circulating and sputum eosinophil counts, and decrease exhaled NO.[1] Clinical effects include improvement in $FEV_1$ and protection from EIB and allergen-induced bronchospasm. Improvement in pulmonary function can be detected after the first dose and reaches a peak after a few weeks of treatment. However, the montelukast effect on asthma control is not as great as that from an ICS, as measured by improvement in $FEV_1$, symptom control, and reduction in inflammatory markers.[130] Trials in children with slightly more severe disease based on lower $FEV_1$ also showed significantly greater improvement in pulmonary function measures, symptom reduction, and need for rescue SABA with fluticasone compared with montelukast.[131]

Predicting which patients will have a more favorable response to montelukast versus ICSs has proven difficult. However, a study examining the rate of response of children with mild asthma to ICS, montelukast, or both demonstrated that 23% responded to fluticasone alone, 5% responded to montelukast alone, 17% responded to both, but 55% responded to neither drug.[132] Children who are older, have had asthma for a longer duration, have a parental history of asthma, have a higher exhaled NO, and have a lower $PC_{20}$ are more likely to respond favorably to ICS treatment compared with LTRA treatment.[133]

Montelukast may provide improved asthma control when combined with other controller medications, such as inhaled steroids. Although study results are somewhat conflicting, most show that the addition of montelukast to an ICS results in modest improvement that is not quite as efficacious as adding an LABA, particularly on pulmonary function outcomes. One pediatric trial demonstrated a small improvement in $FEV_1$ (6.0% montelukast, 4.1% placebo, $P < .01$) and in the need for rescue bronchodilator use (1.65 puffs/day montelukast, 1.98 puffs/day placebo, $P < .013$) when montelukast was added to a regimen of low-dose BUD.[134]

Adverse effects of montelukast have been relatively minor and mainly consist of headache, abdominal pain, vivid dreams, and sleep disruption. Reports of behavioral changes (e.g., moodiness, depression) and an unsubstantiated association with a suicide report have led to a label change including behavioral changes as a possible side effect of treatment with montelukast. There are several case reports of adults developing Churg-Strauss syndrome when treatment with montelukast was instituted and ICS treatment withdrawn. Since the majority of these patients had what was considered to be severe steroid-dependent asthma, it is believed that the development of systemic vasculitis was actually the emergence of an underlying disease as a result of steroid withdrawal and less likely a result of the direct action of montelukast. Care should be taken, however, if montelukast is used in an attempt to decrease or discontinue oral steroids in a patient with presumed severe asthma.

## Long-Acting Muscarinic Antagonists

Short-acting quaternary anticholinergic medications such as ipratropium bromide have been used for decades as bronchodilators in the treatment of asthma. Tiotropium, a long-acting muscarinic receptor antagonist with a duration of action of 24 hours, which has been a mainstay of COPD treatment, has recently been approved for use in patients with severe persistent asthma not controlled with ICS. There are five subtypes of muscarinic receptors, three of which are found in human airways ($M_1$, $M_2$, $M_3$). All three types of muscarinic receptors mediate neurally induced bronchoconstriction. Tiotropium has a high affinity for M receptors but dissociates very slowly from type M1 and M3 receptors, resulting in prolonged prevention of bronchoconstriction and a 24-hour bronchodilatation effect.[96]

Although there is a paucity of studies compared to those examining glucocorticoids, the available data have consistently shown that tiotropium, when added to ICS or ICS and LABA, resulted in improved lung function, which was maintained even after ICS dose reduction and LABA discontinuation.[135,136] In fact, when used in combination with low-dose ICS, tiotropium is more effective at improving lung function than doubling the ICS dose and is noninferior to LABA as measured by decrease in symptom days, improvement in quality of life, and asthma control score.[136–138] When added to medium-dose ICS, tiotropium continued to result in improvement in lung function[135,136,138,139] The effect on lung function is comparable to that of salmeterol, and there may also be acute bronchodilatation in patients with poorly controlled symptoms.[137,140,141] In addition, tiotropium in combination with ICS and LABA decreased the risk of severe exacerbations, and extended the length of time to the first exacerbation.[139,142]

Most studies of tiotropium in asthma have been conducted with adults, however more recently there have been trials with children that show similar benefits and an excellent safety profile.[138,139,143,144] Tiotropium has been added as recommended therapy for children aged ≥ 12 years in steps 4 and 5 of the most recent version of the GINA guidelines.[72] Tiotropium is available in two doses via soft mist MDI (Respimat), 2.5 μg and 1.25 μg per actuation. Two puffs of the 1.25 μg dose administered once daily has been approved in the United States for children with asthma, although higher doses have been approved for use in COPD.[145] Peak effect on $FEV_1$ occurs within 1–3 hours after dosing. Other anticholinergic agents such as umeclindinium and aclinidium are currently used in treatment of COPD but have not yet been adequately studied in asthma.

## Methylxanthines: Theophylline

Although methylxanthines have been used for the treatment of asthma since the early part of the 20th century, their role in managing acute and chronic asthma has become very restricted. Theophylline is now considered a second- or third-line medication, largely because it is a poor acute bronchodilator; it has a narrow therapeutic index and significant adverse effects, and antiinflammatory drugs have replaced it. It does have the advantage of being inexpensive and can be administered in a long-acting oral formulation. Theophylline is a phosphodiesterase inhibitor that causes smooth muscle relaxation and bronchodilatation. However, theophylline can also act centrally as a respiratory stimulant and may also increase diaphragmatic contractility and help prevent diaphragmatic fatigue. In addition, more recent data suggest that it blocks histone deacetylation, which may be important to the action of corticosteroids and modulation of inflammatory mediators; further work is necessary to confirm the clinical relevance of this action. Low-dose theophylline (amounts sufficient to cause a serum level of 5–10 mg/mL) may be helpful in some patients for chronic management. The addition of theophylline to ICSs may have a steroid-sparing effect in some patients, but it is less effective than adding a long-acting β agonist.[146–149] However, adverse effects, such as tremor, gastric irritation, gastrointestinal hemorrhage, agitation, and convulsions, may occur at even relatively low serum concentrations. Also, many commonly used medications can interfere with theophylline metabolism, resulting in clinically significant elevation (e.g., some macrolide and fluoroquinolone antibiotics) or lowering (carbamazepine) of serum concentrations. Febrile viral illnesses may also substantially increase serum concentrations. Careful monitoring of serum concentration is mandatory when doses above 10 mg/kg per day are administered to children and adolescents.

## Biologic Therapy for Asthma

Several novel approaches to asthma therapy involve immune modulation, which may be useful for both the prevention and treatment of asthma. Use of a humanized monoclonal anti-IgE antibody (omalizumab) to complex with and lower the circulating concentration of IgE has demonstrated efficacy in select patients. This drug is approved by the US Food and Drug Administration for use in patients 6 years of age and older. Mepolizumab, a monoclonal antibody to IL-5, resulted in a significant reduction in exacerbations and improvement in quality of life for patients with severe eosinophilic asthma. It is approved in the United States for patients aged 12 years and older. Reslizumab, also an anti-IL-5 antibody, is available in the United States for those asthmatics ≥ 18 years old who have eosinophilic disease. Biologic therapies for asthma are discussed in more detail in Chapter 48.

## Management of Chronic Asthma

The effective management of chronic asthma should focus on (1) identification and elimination of exacerbating or aggravating factors, (2) pharmacologic therapy, and (3) education of the patient and family about the disease and the management skills necessary to avoid and treat acute exacerbations. The goals of management of chronic asthma in children include minimizing symptoms and exacerbations, maintaining normal activities of daily living, maintaining normal or near-normal pulmonary function, and avoiding adverse effects from asthma medications. To achieve these goals, a combination of pharmacologic and nonpharmacologic modalities must be utilized.

Successful asthma management includes appropriate grading of disease control (see Table 45.3). Asthma severity, or the intrinsic intensity of the disease, should be distinguished from asthma control. Patients may have relatively mild asthma that is poorly controlled due to multiple factors, such as inadequate treatment, impaired adherence, or excessive exposure to allergens or irritants. Once appropriate medical and environmental measures are instituted, the asthma may become "mild" in terms of absence of symptoms and normalization of pulmonary function while taking low doses of a controller medication. Patients who demonstrate a progressive decline in pulmonary function, frequent exacerbations, and persistent or recurrent symptoms in spite of regular use of controller medication and environmental controls have more severe disease.

The emphasis in most guidelines is now placed on establishing asthma control, which includes minimizing impairment (symptoms) and avoiding risk of serious exacerbations, medication adverse effects, loss of lung function, and (in the case of children) reduction in lung growth. As discussed earlier in the chapter, other biomarkers of airway inflammation (eNO, sputum, or peripheral blood eosinophils) may add additional useful data for grading asthma severity and guiding treatment to improve control. Several brief, validated questionnaires can be used in most clinical or community settings to provide a rapid assessment of asthma control (see the section on "Other Measures for Assessing Asthma Severity and Control" earlier in the chapter). Although the utility of the scores as a single measure is established, the responsiveness to change over time, collection of data in relation to recent exacerbations, and seasonal variability all need further evaluation.

The risk domain of control includes exacerbations that are severe enough to warrant treatment with oral corticosteroids, emergency medical care, or hospitalizations. There are limited data that are useful in predicting future exacerbations; however, there is an inverse relationship between $FEV_1$ and the risk of developing an exacerbation in the subsequent year. In addition, having one severe exacerbation is a strong risk factor for a subsequent episode in the same year. Data are lacking to accurately correlate the number and severity of exacerbations with degree of asthma control. More than one exacerbation per year indicates asthma control is inadequate and the frequency and severity of exacerbations increases with worsening control. Patients should start treatment at the step most appropriate to the initial severity grading (or control level for those already receiving treatment) of their asthma.

The most recent National Asthma Education and Prevention Program (NAEPP) guidelines continue to list four severity classifications: intermittent, mild, moderate, and severe persistent, but have expanded the stepwise treatment algorithm to six steps while the GINA guidelines have five steps (Fig. 45.5). Immunotherapy continues to be recommended for children who are at steps 2–4, have documented allergy, and have persistent symptoms. However, immunotherapy is most likely to be effective for those with single allergen sensitization, and this evidence for efficacy is strongest for animal dander, house dust mites, and pollen. The two added treatment steps for adolescents and adults are aimed at those who are allergic, have refractory symptoms in spite of high-dose ICSs, plus another antiinflammatory controller. At these steps 5 and 6, recommended additional treatment includes oral corticosteroids and omalizumab for those older than 12 years of age who are also allergic. Mepolizumab, which was not available at the time of publication for the NAEPP guidelines, should now be considered for patients 12 years of age and older who have eosinophilic asthma and are not well controlled, with high-dose ICS and another controller. The GINA guidelines for asthma management have included tiotropium as add-on therapy for patients requiring step 4 or step 5 therapies in the 2015 revision.[72] The treatment steps are used in conjunction with control levels. Patients who achieve good control are maintained at the lowest step level possible. Those with not well-controlled or poorly controlled asthma receive step-up treatment until control is achieved. Step-down to a lower treatment level should be attempted once control is maintained for at least 3 months and no other contraindications for reducing medication exist (e.g., persistent allergen exposure, entry into high-risk season). Patient education, environmental controls, and management of comorbid conditions are stressed at all steps. In addition, it is critical that all patients and their adult caregivers be thoroughly trained in the appropriate use of the specific medication delivery devices and monitoring tools prescribed (e.g., MDI, DPI, nebulizer, PEFR meter). In addition to obtaining spirometry at the time of initial assessment, at least annual monitoring of lung function in children age 5 years and older is recommended for all levels of asthma severity; however, spirometry is more likely to be of value for those with more severe disease and low lung function at baseline. Spirometry should also be obtained during periods of progressive or prolonged loss of asthma control.[1]

## Intermittent Asthma

Children with intermittent asthma or EIA have brief episodes of wheeze or cough that are easily relieved with SABA treatment and occur no more frequently than once or twice per week. Treatment is with the as-needed use of an inhaled SABA agonist.[1] The usual dose of inhaled racemic albuterol is 2–6 puffs (90 μg/puff) every 3–4 hours or 0.15 mg/kg (usual dose 2.5 mg, maximum 5 mg) nebulized from a small-volume nebulizer in 2 mL of saline. Other SABAs (e.g., levalbuterol and terbutaline) may also be used, and it is unlikely that there is any significant difference in efficacy among the drugs. Numerous studies have demonstrated that administration of albuterol by MDI is equally effective as that given by nebulizer.[1,65] Moreover, use of an MDI by older children (with or without a valved holding chamber [VHC]) is far more convenient and less expensive than a nebulizer. EIA may be prevented to a large extent with inhalation of albuterol (or formoterol) 5–20 minutes before exercise. Montelukast taken 1–2 hours before exercise may also help prevent EIB.

## Mild Persistent Asthma

The majority of asthmatics are classified as having mild persistent asthma, based on symptoms that occur several times per week, but not daily; infrequent nocturnal symptoms; and normal pulmonary function. The primary treatment of mild persistent asthma is a low-dose ICS. Data from multiple studies support the superior efficacy of ICSs compared with other treatments in improving pulmonary function, reducing symptoms and need for rescue medications, and improving bronchial hyperreactivity. As outlined previously, the safety profile for ICSs given at low dose is excellent. There are few data to suggest that one type of ICS will offer significantly greater benefit than the others, but the dose equivalency and ranges for low, medium, and high doses differ (see Table 45.5). BDP, fluticasone, and BUD have been extensively studied in children for many years, are available in easy-to-use devices (MDIs or DPIs), are well tolerated by most patients, and the adverse event profile is well understood. Large comparative effectiveness trials, particularly in children, are sparse. However, a retrospective observational study that used a large general practice research database in the United Kingdom examined asthma control in newly treated asthmatics 5–60 years of age. Using a matched cohort analysis, more than 2600 patients, including 773 children age 5–12 years of age who were prescribed HFA BDP, or FP, were followed for 2 years. Although more than 80% of the patients in each group achieved control, patients who were treated with or received step-up treatment with BDP were more likely to be controlled (adjusted odds ratio 1.30; 95% CI, 1.02–1.65).[150] However, the control measure used was a composite of largely risk domain elements (i.e., exacerbation, oral steroid use, hospitalization) and probably missed impairment domain measures (symptoms). Older inhaled steroids (e.g., flunisolide, triamcinolone) with lower topical potency are used less frequently. Newer inhaled steroids, such as mometasone and ciclesonide, are currently labeled for use in the United States for children 12 years of age and older.

Although chronic daily dosing of ICS is the general recommendation to maintain good asthma control, other strategies have been investigated and hold promise as valid alternatives. There are a few studies that have compared chronic daily inhaled steroid use with intermittent treatment. There was no difference in morning PEFR or asthma exacerbations between those that used daily inhaled steroids and those that used them as needed, but daily use of inhaled steroids resulted in better asthma control based on symptom days, asthma control scores, FeNO, and eosinophils.[151,152] This strategy appears to benefit the risk domain more than the impairment (daily symptom) domain; therefore if daily symptom burden reduction is more important than infrequent and mild exacerbation reduction, a daily treatment strategy may be preferable.

Implications for pediatric asthma management with intermittent steroid use may be even greater, since the risk of growth suppression is higher in children. A recent study compared daily with as needed use of BDP in children with mild asthma who were previously well controlled while taking daily low-dose ICS. In this multicenter study, children ages 5–18 were randomly assigned to one of four treatment groups: placebo twice daily with albuterol plus placebo as rescue, placebo twice daily with albuterol plus BDP as rescue, BDP twice daily with albuterol plus placebo as rescue, or BDP twice daily with BDP plus albuterol as rescue. Children who received inhaled steroids daily had fewer exacerbations than children who used no inhaled steroids and albuterol alone as rescue (28% vs. 49%, $P = .03$). Children who received BDP daily and as a rescue (with albuterol) or as rescue (with albuterol) only had fewer exacerbations than the placebo group, but the results did not reach statistical significance (31% for BDP daily and as rescue with albuterol, $P = .07$; 35% for BDP as rescue only with albuterol, $P = .07$). Notably, linear growth was over 1 cm lower in both groups who received inhaled steroids daily compared with the group which received no ICS ($P < .0001$). There was no difference in growth between the placebo group (no ICS) and those who received BDP only as a rescue medication ($P = .26$).[153] These data suggest that some patients with mild asthma of relatively new onset may achieve adequate control with intermittent ICS use after a period of stabilization with continuous ICS treatment, and with less risk of minor growth suppression. However, daily use of an ICS, even when tapered to low dose, provides the best overall control, particularly in the exacerbation risk domain.

An alternative treatment is an LTRA, such as montelukast. This drug has the advantage of once-a-day oral administration and only uncommon mild adverse effects (i.e., nausea, headache, vivid dreams). However, numerous comparative studies indicate that ICSs provide superior asthma control.[133,154] Although the current NAEPP guidelines still list cromolyn, nedocromil, and theophylline as alternative treatments, nedocromil and cromolyn have limited availability (neither is available for inhalation in the United States) and efficacy, while theophylline is less well tolerated.

# Moderate Persistent Asthma

Children who have daily symptoms, nocturnal symptoms more than weekly, and mild obstruction on pulmonary function have moderate persistent asthma. Children who continue to experience symptoms or exacerbations while being treated with low-dose ICSs should have a step up in treatment. Current recommendations for treatment include increasing the ICS dose to the moderate range, or continuing the low-dose ICS and adding a second controller drug with a complimentary mechanism of action. As discussed earlier in the chapter, the dose response curve for ICSs reaches a plateau at relatively modest doses, as determined by pulmonary function and bronchial hyperreactivity measures. However, certain patients may derive benefit in both the impairment and risk domains when the ICS dose is increased to the moderate range. LABAs are the current add-on drugs of choice because of the large body of evidence from randomized controlled trials that indicate efficacy and effectiveness. In older children and adults, the addition of a LABA to a low-dose ICS results in greater improvement in pulmonary function and reduction in symptoms than a further increase in steroid dose. The availability of a fixed-dose combination of fluticasone and salmeterol or BUD and formoterol in a single inhaler make this combination attractive. An alternative is to raise the dose of the inhaled steroid alone to the medium range; this is the current recommended strategy for children younger than 4 years of age,[1] but is a secondary option in older children. When concerns exist about the use of LABA or medium-dose ICSs, the addition of an LTRA (e.g., montelukast) should be considered. Although the additive effect of LTRA is more limited, the safety profile may be viewed as more favorable. LTRA, when added to inhaled BUD in one study, resulted in a modest improvement in PEFR and a reduction in need for SABA.[134] Low-dose theophylline is another low-cost add-on medication that may also help improved symptom control. Data indicate that the latter two add-on medications are also effective in improving asthma control, but less so than the addition of a LABA. Use of theophylline as a single daily dose of a time-release preparation can be well tolerated and is typically less expensive than using a LABA or LTRA. Any patient who has deterioration of lung function while using a LABA chronically should have an alternative medication prescribed. Whatever combination of medications is used, attempts should be made at regular intervals to decrease the ICS dose to the lowest level that adequately controls symptoms and maintains normal pulmonary function. Children in this category will benefit from referral to a pulmonologist and may also require ongoing specialty care.

## Severe Persistent Asthma

Approximately 5%–10% of patients will have severe persistent asthma as described by persistent daily symptoms, frequent nocturnal awakenings, and a moderate or severe obstructive pattern on pulmonary function testing. These symptoms may occur in spite of treatment with high-dose ICSs, LABAs, and/or a LTRA or low-dose theophylline. Patients with the most severe disease have inadequate response to even high doses of ICS in combination with other available controller medications. If there is no response, oral corticosteroids are the next recommended treatment step. It may be necessary to administer a short course (<10 days) of daily dosing (40–60 mg/day) and then a longer every-other-day course at the lowest effective dose (0.5 mg/kg every other day). Before instituting such therapy, a thorough search for remediable exacerbating factors or comorbid conditions (e.g., sinusitis, persistent allergen exposure, poor compliance, GER, VCD) should be sought. As soon as symptoms are controlled, the lowest possible oral steroid dose at which symptom control is maintained should be administered. Although a single morning dose is generally preferred to minimize systemic side effects, some patients with severe or refractory symptoms may benefit from twice-daily dosing. Children receiving chronic oral corticosteroid therapy should be carefully monitored for development of adverse effects, such as hypertension, cataract formation, hyperglycemia, loss of bone mineral content, and impaired linear growth. Systemic corticosteroids may be given in the presence of acute viral infections, otitis media, or pneumonia and will not result in worsening infections. However, patients who develop varicella while taking systemic corticosteroids, or who take the medication during the incubation period, should have the steroid dose reduced to the minimum tolerable to control the asthma and should also be provided adrenal replacement. In addition, consideration should be given to administering acyclovir for 5–7 days, and the patient should be carefully observed for signs of severe or disseminated disease. If there has been a significant exposure to varicella identified within the previous 96 hours, passive immunization with varicella zoster immune globulin can be offered. Children with persistent asthma should receive varicella vaccine if they have not previously contracted the disease.

A proportion of severe asthmatics may be steroid resistant; in one series of patients with refractory asthma, 25% were determined to be steroid resistant. Such patients may have altered steroid metabolism or receptor dysfunction. A careful evaluation and specialized pharmacokinetic and cellular studies may be needed to ascertain the etiology of the defect. Patients deemed to be steroid resistant may be candidates for alternative therapies, such as omalizumab, mepolizumab, or other immune modulator treatments. Children with severe asthma should receive routine care from a specialist. Frequent visits to assess symptom control, pulmonary function testing, quality of life, patterns of medication use, presence of comorbid conditions, adverse effects caused by treatment, and adherence to treatment regimen are essential. Severe asthma is discussed in more detail in Chapter 46.

## Holding Chambers and Spacer Devices

A number of studies indicate that as many as 80% of patients use MDIs incorrectly, even after appropriate instruction, and many residents, physicians, and nurses are unable to teach patients correctly. Proper steps are given in Table 45.6. Although there is a relatively small difference in the amount of medication that reaches the lower respiratory tract from a properly used MDI alone compared with an MDI plus a VHC (10% for MDI alone, 15% for MDI plus holding chamber), a VHC helps ensure that the maximum possible dose reaches its target. The holding chamber also minimizes deposition of the medication in the mouth and oropharynx, a particularly important feature when ICSs are prescribed. There are several important points to remember when using a VHC. The child should take a slow deep inspiration and try to hold his or her breath for 5–10 seconds after inhalation of the medication. Only one medication should be dispensed into the chamber at a time, although the same chamber may be used for other medications. A holding chamber that is of at least 150 mL volume and that accommodates the MDI canister in its original boot is preferable to one that requires the canister to be inserted into an adapter. The latter chambers may not result in accurate dispensing of medication because of a mismatch between the adapter and the actuator. Newer holding chambers are made of antistatic plastics or metal that minimizes static charge, which can cause excessive retention of medication in the chamber. Washing the chamber with a mild detergent and air drying can also help prevent static charge.

See www.cdc.gov/asthma/inhaler_video/default.htm for a video demonstrating proper VHC (spacer) device use.

### Table 45.6

### Directions for Use of a Metered-Dose Inhaler, With and Without a Spacer

| MDI Use Without Spacer Device | MDI Use With Spacer Device |
|---|---|
| 1. Shake canister for 5 s. | 1. Shake canister for 5 s. |
| 2. Position finger on top of canister for support. | 2. Attach canister to spacer. |
| 3. Patient exhales normally (to FRC). | 3. Patient exhales normally (to FRC). |
| 4. Place mouthpiece 2 cm in front of open mouth around tube (may place in mouth if coordination is a problem). | 4. Place mouthpiece in mouth and close lips. |
| 5. Begin slow inspiration. | 5. Activate canister. |
| 6. Activate canister. | 6. Begin slow inspiration. |
| 7. Complete inhalation over several seconds. | 7. Complete inhalation over several seconds. |
| 8. Hold breath for 10 s. | 8. Hold breath for 10 s. |
| 9. Wait 30–60 s, and repeat steps 2–8 for prescribed number of inhalations. | 9. Wait 30–60 s, and repeat steps 2–8 for prescribed number of inhalations. |

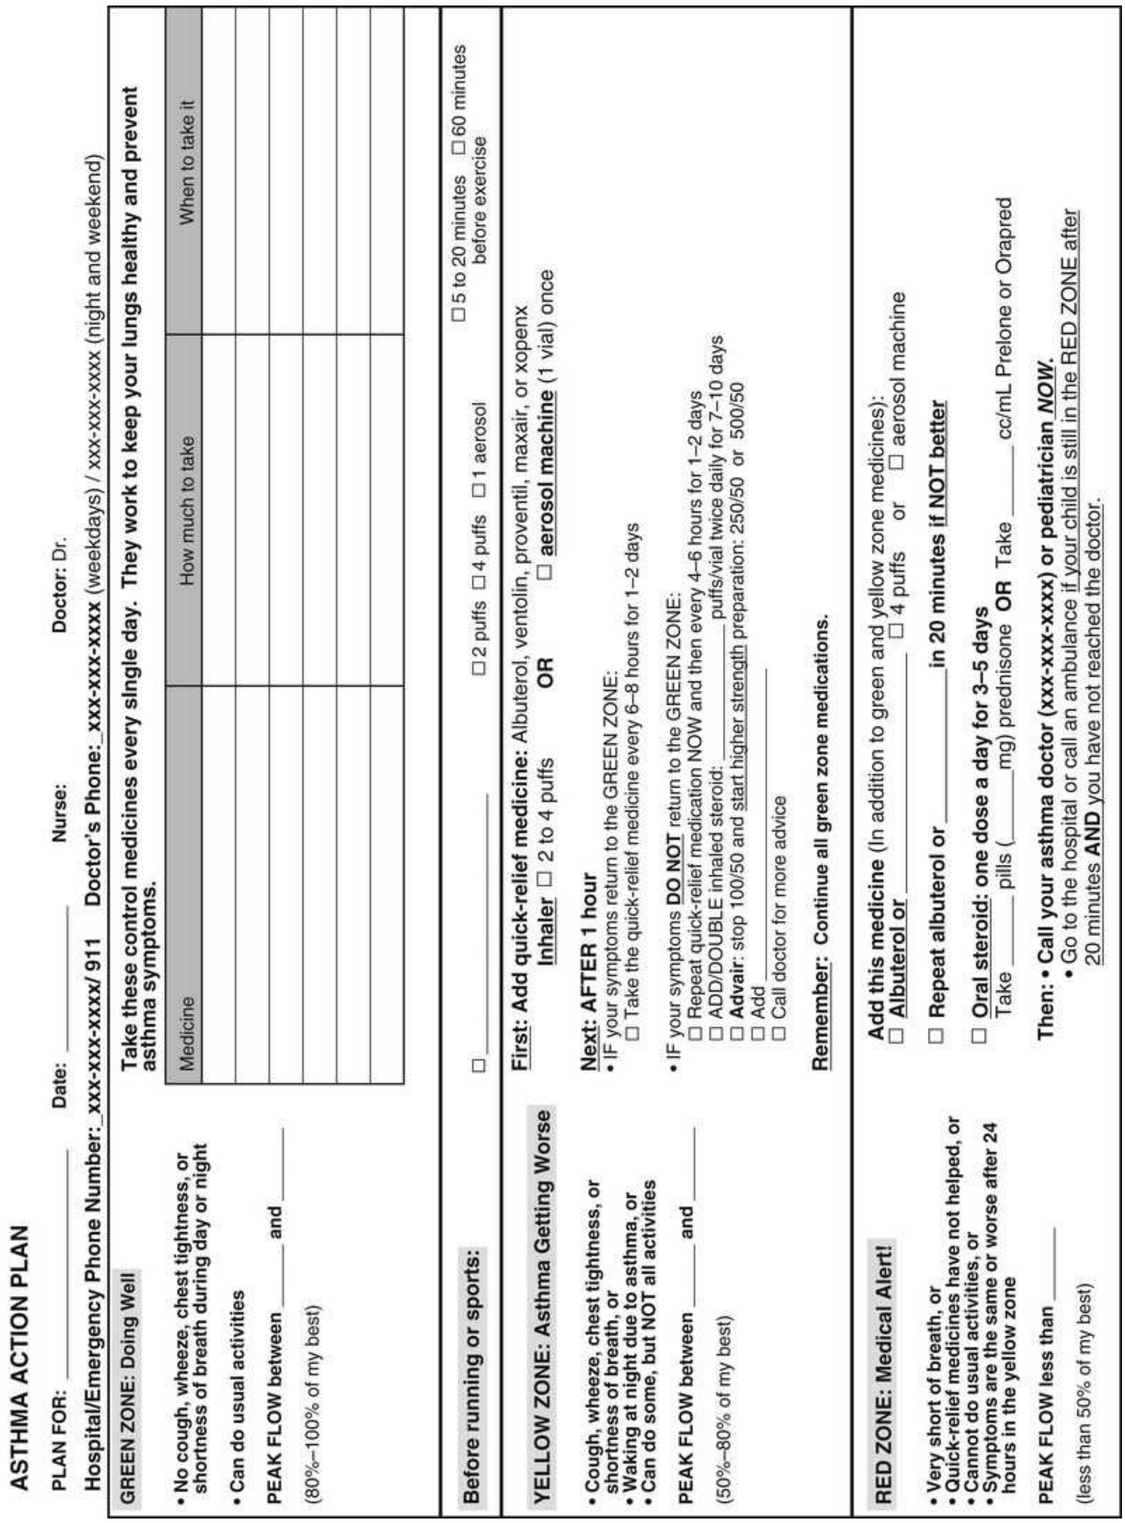
*FRC*, Functional Residual Capacity; *MDI*, metered-dosed inhaler.

# Peak Expiratory Flow Rate Monitoring

Home monitoring of PEFR has been advocated for optimal management of the patient with moderate to severe persistent asthma, but the utility remains somewhat limited. PEFR is only moderately correlated with $FEV_1$, and other measures such as $FEF_{25–75}$, $FEF_{50}$, or mid-maximal expiratory flow (MMEF) that can be used as a valid measure of obstructive ventilatory defect. The degree of diurnal and day-to-day PEFR variability has been proposed for years as a marker of asthma severity and airway hyperreactivity. However, the correlation between PEFR variability and airway hyperreactivity is only moderate. Moreover, the correlation of PEFR variability with other clinical markers of asthma disease activity or severity remains unclear. PEFR probably has its greatest value when used repeatedly to indicate severity of an acute asthma exacerbation and the subsequent response to treatment. Normal PEFR ranges are determined by the patient's age, sex, and height, and are readily available. Some patients have PEFR readings well above, or in some cases below, published standards. For this reason, an individual patient's personal best reading is often used as a target. It is important that the personal best be determined only when efforts have been made to ensure that asthma is optimally managed at the time the measure is made; this may require short courses of oral corticosteroids and other antiinflammatory medications.

Small portable handheld PEFR devices can provide an objective measure of lung function in the home or school setting. Currently available devices record measurements electronically and some also measure $FEV_1$ and $FEV_6$. Patients may use the PEFR reading to alter medications according to a predetermined plan. Patients and families must know when and how to use the PEFR meter, how to interpret the measurement and respond to the reading, and when to communicate with their physician. Some of these steps can be obviated with the use of a commercial system that uses a recording PEFR meter capable of transmitting a longitudinal report via phone line or the Internet to the managing physician. Although earlier guideline recommendations were that all patients with asthma use a PEFR-driven asthma action plan, studies suggest that routine use of PEFR monitoring is more likely to benefit those with more severe or unstable disease and is more likely to be used intermittently (around the time of increased symptoms or seasonally), rather than continuously.[1,72]

After determining the target, normal, or personal best PEFR reading, a care plan incorporating the measure can be made. Sample plans may be obtained from readily available sources (Fig. 45.6).[1]



**ASTHMA ACTION PLAN**

**PLAN FOR:** ______________________ **Date:** ______________ **Nurse:** **Doctor:** Dr.

**Hospital/Emergency Phone Number:_xxx-xxx-xxxx/ 911** **Doctor's Phone:_xxx-xxx-xxxx** (weekdays) / xxx-xxx-xxxx (night and weekend)

**GREEN ZONE: Doing Well**

- **No cough, wheeze, chest tightness, or shortness of breath during day or night**
- **Can do usual activities**

**PEAK FLOW between** ______ **and** _______

(80%–100% of my best)

**Take these control medicines every single day. They work to keep your lungs healthy and prevent asthma symptoms.**

| Medicine | How much to take | When to take it |
|---|---|---|
| | | |
| | | |
| | | |
| | | |
| | | |
| | | |

**Before running or sports:** ☐ ________________________ ☐ 2 puffs ☐ 4 puffs ☐ 1 aerosol ☐ 5 to 20 minutes ☐ 60 minutes before exercise

**YELLOW ZONE: Asthma Getting Worse**

- **Cough, wheeze, chest tightness, or shortness of breath, or**
- **Waking at night due to asthma, or**
- **Can do some, but NOT all activities**

**PEAK FLOW between** ______ **and** _______

(50%–80% of my best)

**First: Add quick-relief medicine:** Albuterol, ventolin, proventil, maxair, or xopenx
**Inhaler** ☐ 2 to 4 puffs **OR** ☐ **aerosol machine** (1 vial) once

**Next: AFTER 1 hour**

- IF your symptoms return to the GREEN ZONE:
  - ☐ Take the quick-relief medicine every 6–8 hours for 1–2 days
- IF your symptoms **DO NOT** return to the GREEN ZONE:
  - ☐ Repeat quick-relief medication NOW and then every 4–6 hours for 1–2 days
  - ☐ ADD/DOUBLE inhaled steroid: _____________ puffs/vial twice daily for 7–10 days
  - ☐ **Advair**: stop 100/50 and start higher strength preparation: 250/50 or 500/50
  - ☐ Add _____________________________
  - ☐ Call doctor for more advice

**Remember: Continue all green zone medications.**

**RED ZONE: Medical Alert!**

- **Very short of breath, or**
- **Quick-relief medicines have not helped, or**
- **Cannot do usual activities, or**
- **Symptoms are the same or worse after 24 hours in the yellow zone**

**PEAK FLOW less than** _______

(less than 50% of my best)

**Add this medicine** (In addition to green and yellow zone medicines):
☐ **Albuterol or** ______________________ ☐ 4 puffs or ☐ aerosol machine

☐ **Repeat albuterol or** ______________ **in 20 minutes if NOT better**

☐ **Oral steroid: one dose a day for 3–5 days**
Take ______ pills (______mg) prednisone **OR** Take ______ cc/mL Prelone or Orapred

**Then: • Call your asthma doctor (xxx-xxx-xxxx) or pediatrician *NOW*.**
• Go to the hospital or call an ambulance if your child is still in the RED ZONE after 20 minutes **AND** you have not reached the doctor.

**FIG. 45.6** Sample treatment plan form for management of chronic asthma. Instructions may use peak expiratory flow rate monitoring in addition to symptoms to assess the need for additional treatment.

The zones are generally defined as follows:

Green: PEFR 80%–100% predicted/personal best; all clear, no symptoms.

Yellow: PEFR 50%–80% predicted/personal best; indicates worsening airway obstruction or an impending attack. Symptoms include slowed play, intermittent cough, wheeze, and dyspnea.

Red: PEFR less than 50% predicted/personal best; indicates significant airway obstruction and need for immediate medical attention. Symptoms include severe dyspnea, retractions, continuous wheeze, or cough.

There are limitations to PEFR monitoring efficacy. The PEFR is effort-dependent, and some children learn how to deliberately adjust the reading artificially high or low by the effort used. In addition, PEFR only measures obstruction in the large central airways; many asthmatics have a normal or near-normal PEFR, but significant obstruction in the small airways or as measured by $FEV_1$ or $FEV_1$/FVC. Moreover, it is unclear that long-term PEFR use as part of an asthma action plan results in better outcomes than monitoring symptoms without PEFR and adjusting therapy accordingly.[13] Symptom-based asthma action plans are equally effective as those based on peak flow monitoring.

## Nonpharmacologic Measures

Nonpharmacologic interventions necessary for successful management include formation of an effective partnership with a knowledgeable health care provider, frequent monitoring of asthma symptoms and response to therapy, objective measures of pulmonary function, and avoidance of asthma triggers. Trigger avoidance is important, yet patients are often unaware of specific triggers or how to put environmental controls in place. Environmental exposures (e.g., diesel particulates, ozone, and sulfur dioxide) are likely to be more pronounced in those living near highways, on bus lines, or near certain industrial plants. For the indoor environment, dust mites, cat and dog dander, mold, and, in the inner city, cockroach antigen have all been strongly linked to asthma exacerbations and morbidity. Removal of these allergens can result in reduced symptoms and airway hyperresponsiveness. However, it is difficult to reduce indoor allergen burden below the threshold likely to induce symptoms without a multifaceted approach. The use of room air filters and special cleaning agents have some appeal but are not as effective as keeping ambient humidity low (30%–40%), putting plasticized covers on pillows and mattresses, washing bedding weekly in hot water, and removing carpeting. A recent study suggested that application of dust covers alone is not effective in improving airway function. Removing pets from the bedroom and ideally from the household is also desirable. Exterminating roaches is difficult, but the use of integrated pest management strategies and eliminating water sources can be effective. For all asthmatics, avoidance of passive exposure to cigarette smoke is of paramount importance.

The Inner-City Asthma Study utilized a multidimensional environmental intervention that instructed families on providing a “safe sleeping zone” for the asthmatic child. Pets, dust, and other irritants were barred from the sleeping area, and HEPA room filters and vacuums were provided to all. In addition, specific strategies to reduce mold and roaches were implemented in households where dust sampling revealed high levels. This integrated and individualized strategy resulted in significant allergen reduction and improvement in symptom-free days over the yearlong intervention and beyond.[155] Another trial optimized asthma medical care and control and then provided a mold and moisture remediation program that removed existing mold and repaired construction defects and leaks that promoted the mold problem. Compared with those who lived in homes not remediated, the children in the intervention group had more symptom-free days and fewer serious exacerbations.[156] A multicenter study in Europe demonstrated that use of a device that provides temperature controlled, laminar air flow to reduce inhalant allergen exposure is associated with improved quality of life (as measured by the Asthma Quality of Life Questionnaire) and decreased FeNO level.[157]

Use of ancillary personnel (e.g., a social worker who can conduct formal risk assessment of psychosocial, economic, and school-related risks) may be of great benefit in improving asthma control.

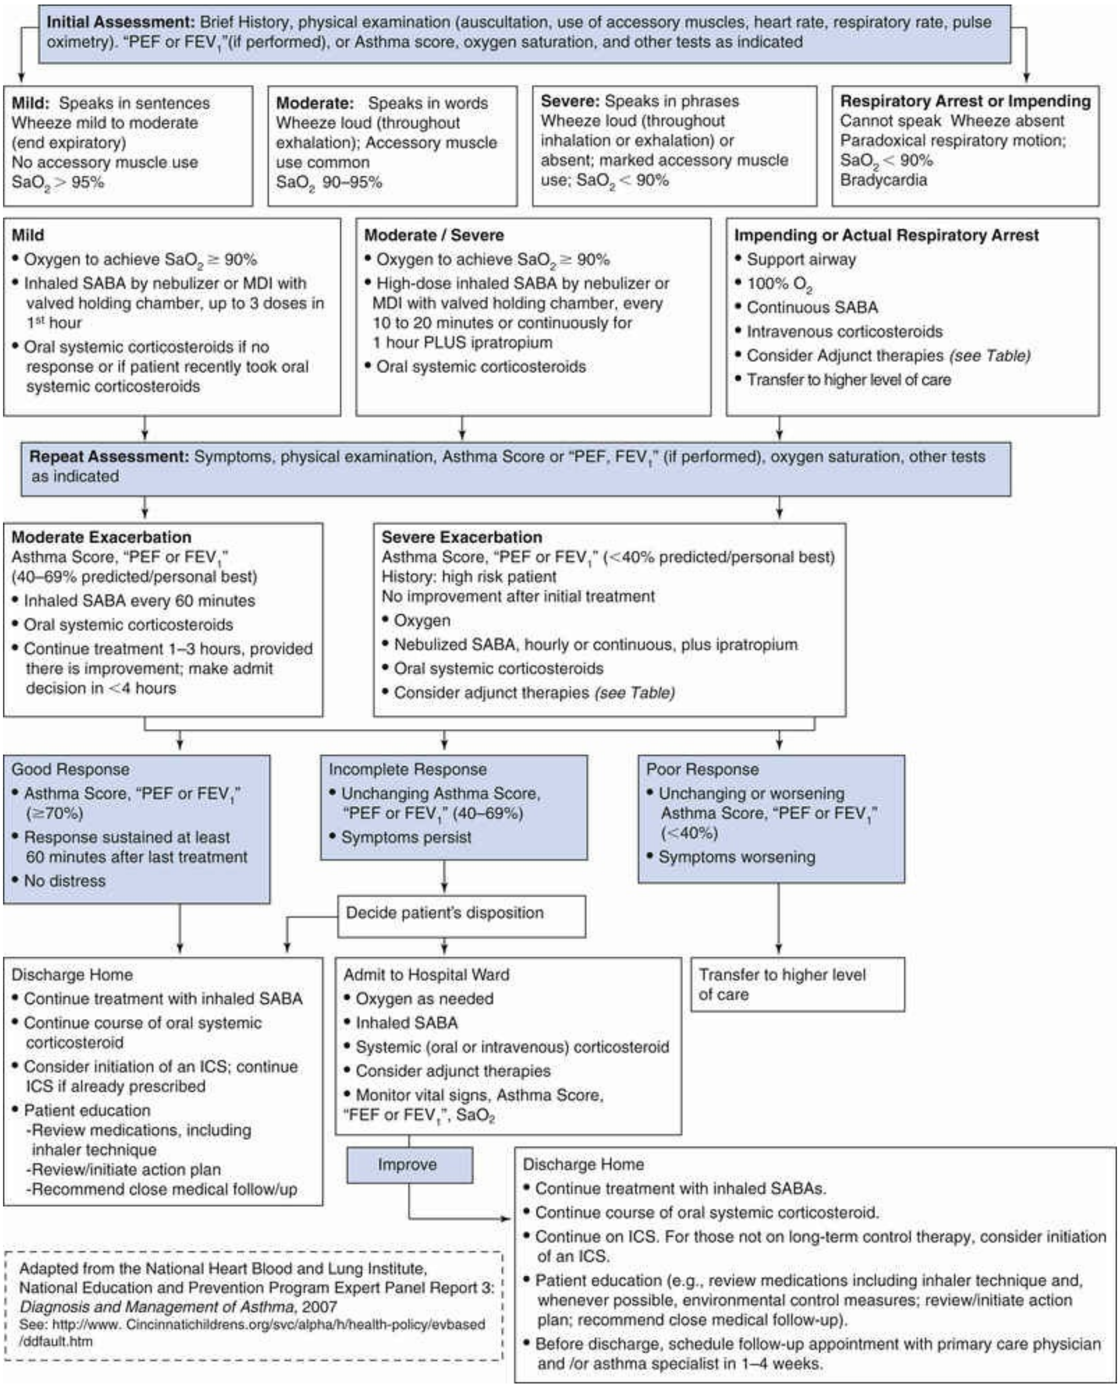
Social determinants of chronic disease management often relate to, or operate through, poverty. Substandard housing, limited access to high-quality medical care, and transportation and child care barriers can all contribute to poor asthma control in patients from lower socioeconomic groups. Impaired maternal mental health, lack of social supports, and child behavior problems may all contribute to poor adherence and asthma control.

Adherence to a treatment regimen is key to successful asthma management. Adherence differs from compliance, in that adherence stresses the role of the patient and family in helping develop a treatment program and contributing to the strategies necessary to utilize the treatment plan. Compliance implies that a patient must utilize a plan derived by the physician; failure to do so indicates that the patient is at fault and irresponsible. The factors that contribute to adherence are complex and incompletely understood. It is difficult to predict which patients will have good adherence, and it is not well correlated with race, gender, or intelligence. Moreover, many patients overreport good adherence in an attempt to please the physician. Adherence to suggested medical treatment for asthma often ranges from 30% to 70% use of prescribed medicine. Families should be encouraged to identify areas of a treatment regimen that might offer difficulty, concerns they have about medications, and lifestyle issues that might impair adherence. Physicians must be willing to provide suitable alternatives (e.g., medications, dose schedules). Regularly scheduled office visits should be conducted to evaluate the success of the treatment plan and offer the patient the opportunity to voice concerns and ask for help. When a child or the parents fail to adhere, the physician should try to find out the reasons and to work out a practical solution that is acceptable to the patient and family. Use of motivational interviewing techniques and shared decision-making strategies can often provide better results than direct reminders.

Patients must be given ready access to medical advice (e.g., over the telephone), including how to deal with school-related asthma management and behavior problems. Other technologies, such as text messaging, email, videoconferencing, and social networking, are also gaining popularity as ways to communicate with patients. Most importantly, parents and patients must learn that frequent symptoms and limitation of lifestyle due to illness should not be accepted; a symptom-free existence should be the goal.

## Management of an Acute Episode

Acute asthma in children can occur as a mild illness that responds promptly to bronchodilators, or it can develop into a medical emergency over a matter of a few hours or days. Failure to respond to aggressive home treatment mandates further evaluation and treatment in the physician's office or a hospital emergency department. Use of treatment algorithms and guidelines provide useful infrastructure on which to base treatment, referral, and admission decisions (Fig. 45.7).



Initial Assessment: Brief History, physical examination (auscultation, use of accessory muscles, heart rate, respiratory rate, pulse oximetry). "PEF or FEV1"(if performed), or Asthma score, oxygen saturation, and other tests as indicated
Mild: Speaks in sentences Wheeze mild to moderate (end expiratory) No accessory muscle use SaO2 > 95%
Moderate: Speaks in words Wheeze loud (throughout exhalation); Accessory muscle use common SaO2 90–95%
Severe: Speaks in phrases Wheeze loud (throughout inhalation or exhalation) or absent; marked accessory muscle use; SaO2 < 90%
Respiratory Arrest or Impending Cannot speak Wheeze absent Paradoxical respiratory motion; SaO2 < 90% Bradycardia
Mild
• Oxygen to achieve SaO2 ≥ 90%
• Inhaled SABA by nebulizer or MDI with valved holding chamber, up to 3 doses in 1st hour
• Oral systemic corticosteroids if no response or if patient recently took oral systemic corticosteroids
Moderate / Severe
• Oxygen to achieve SaO2 ≥ 90%
• High-dose inhaled SABA by nebulizer or MDI with valved holding chamber, every 10 to 20 minutes or continuously for 1 hour PLUS ipratropium
• Oral systemic corticosteroids
Impending or Actual Respiratory Arrest
• Support airway
• 100% O2
• Continuous SABA
• Intravenous corticosteroids
• Consider Adjunct therapies (see Table)
• Transfer to higher level of care
Repeat Assessment: Symptoms, physical examination, Asthma Score or "PEF, FEV1" (if performed), oxygen saturation, other tests as indicated
Moderate Exacerbation
Asthma Score, "PEF or FEV1" (40–69% predicted/personal best)
• Inhaled SABA every 60 minutes
• Oral systemic corticosteroids
• Continue treatment 1–3 hours, provided there is improvement; make admit decision in <4 hours
Severe Exacerbation
Asthma Score, "PEF or FEV1" (<40% predicted/personal best)
History: high risk patient
No improvement after initial treatment
• Oxygen
• Nebulized SABA, hourly or continuous, plus ipratropium
• Oral systemic corticosteroids
• Consider adjunct therapies (see Table)
Good Response
• Asthma Score, "PEF or FEV1" (≥70%)
• Response sustained at least 60 minutes after last treatment
• No distress
Incomplete Response
• Unchanging Asthma Score, "PEF or FEV1" (40–69%)
• Symptoms persist
Poor Response
• Unchanging or worsening Asthma Score, "PEF or FEV1" (<40%)
• Symptoms worsening
Decide patient's disposition
Discharge Home
• Continue treatment with inhaled SABA
• Continue course of oral systemic corticosteroid
• Consider initiation of an ICS; continue ICS if already prescribed
• Patient education
-Review medications, including inhaler technique
-Review/initiate action plan
-Recommend close medical follow/up
Admit to Hospital Ward
• Oxygen as needed
• Inhaled SABA
• Systemic (oral or intravenous) corticosteroid
• Consider adjunct therapies
• Monitor vital signs, Asthma Score, "FEF or FEV1", SaO2
Transfer to higher level of care
Improve
Discharge Home
• Continue treatment with inhaled SABAs.
• Continue course of oral systemic corticosteroid.
• Continue on ICS. For those not on long-term control therapy, consider initiation of an ICS.
• Patient education (e.g., review medications including inhaler technique and, whenever possible, environmental control measures; review/initiate action plan; recommend close medical follow-up).
• Before discharge, schedule follow-up appointment with primary care physician and /or asthma specialist in 1–4 weeks.
Adapted from the National Heart Blood and Lung Institute, National Education and Prevention Program Expert Panel Report 3: Diagnosis and Management of Asthma, 2007
See: http://www. Cincinnatichildrens.org/svc/alpha/h/health-policy/evbased /ddfault.htm

**FIG. 45.7** Treatment algorithm for medical facility management of acute asthma. *FEV*$_1$*,* Forced expiratory volume in 1 second; *ICS,* inhaled corticosteroid; *MDI,* metered-dosed inhaler; *PEF,* peak expiratory flow; *SABA,* short-acting β agonist; *Sa*$O_2$*,* oxygen saturation in arterial blood.

For mild acute asthma (cough, wheeze without dyspnea; PEFR between 50% and 80% predicted), treatment can begin at home or in the physician's office, and the drug of choice is an inhaled SABA, most commonly albuterol, 0.15–0.3 mg/kg per dose (or 2.5–5 mg) given once from a small-volume nebulizer, or preferably, 2–6 puffs (90 μg/puff) of albuterol (using a VHC if necessary) every 20 minutes for 1 hour. A recent study of 226 adults found that use of albuterol plus ipratropium via MDI as rescue medication on an as needed basis for symptoms provided better bronchodilatation, as measured by FEV1, than albuterol via MDI ($P < .0001$).[158] If symptoms resolve, PEFR (if used) improves, and the patient remains well for 3–4 hours, the short-acting bronchodilator can be repeated as necessary, routine medications continued, and contact with the physician considered. Doubling the dose of inhaled steroids at the onset of an exacerbation is no longer recommended, because most studies have not found a clear benefit. Higher (quadruple) doses of inhaled steroids for acute exacerbations may benefit some patients, but the data are limited thus far.[159] Initiating ICSs as a chronic treatment for a steroid-naïve patient during an acute episode is appropriate, but other treatment with a SABA and systemic corticosteroids should still be used as necessary. If symptoms persist and PEFR improves little after the administration of albuterol, the dose of inhaled albuterol should be repeated and a dose of oral steroid (1–2 mg/kg, maximum 60 mg prednisone) should be given. Physician contact is necessary at this point. For the patient with progressive symptoms in spite of all of the listed measures, care should be sought in a medical facility.

In the emergency department, further administration of nebulized albuterol (2.5–5.0 mg) or 4–6 puffs every 20 minutes may be continued for another hour, and an oral corticosteroid dose may be given if not done earlier. Oral steroids commonly administered for acute asthma exacerbations include prednisone and prednisolone. A body of evidence supports the use of dexamethasone. Its longer half-life allows for fewer doses of medications, thereby facilitating patient adherence.[160,161] There is no benefit to giving IV steroids unless the patient cannot tolerate or will not take the oral form. Ipratropium (250 or 500 μg) should also be given every 20–30 minutes by nebulizer for three doses; this may most likely benefit patients with more severe exacerbations of airway obstruction. A subcutaneous (SQ) injection of epinephrine (or terbutaline) can be given if the patient is in severe distress and unable to comply with aerosol therapy. Studies of continuous albuterol nebulization (10–15 mg/hour) have yielded mixed results, although most favor continuous nebulization over intermittent administration. Significant adverse side effects during continuous nebulization protocols in severe acute pediatric asthma are rare, suggesting that this mode of delivery is safe, if not necessarily more effective, and may be more convenient for patient and staff. A study compared continuously nebulized levalbuterol to racemic albuterol and found no significant efficacy or safety advantage, using pharmacologically equivalent doses.[162] These finding were confirmed in a more recent meta-analysis.[163]

Other treatments that may be used in the acute hospital setting include IV magnesium sulfate ($MgSO_4$) and heliox. $MgSO_4$ can act as a smooth muscle relaxant, possibly by blocking calcium-mediated contraction, decreasing acetylcholine release from neuromuscular junctions, and reducing histamine-induced airway spasm. $MgSO_4$ has been utilized for patients who fail to improve significantly following administration of inhaled SABA and systemic corticosteroids. Several studies demonstrate improved pulmonary function, decreased symptoms, and decreased rate of hospitalization following a single infusion of 40–75 mg/kg (maximum 2 g) over a 20-minute period. $MgSO_4$ should strongly be considered in severely ill patients who are in a monitored unit in an emergency department and are failing conventional therapy. Adverse events include flushing, headache, decreased blood pressure, and weakness; the more significant effects are infrequent unless the serum magnesium level rises above twice normal.

Heliox, a mixture of helium (80%) and oxygen (20%), is a specialty gas that is less dense than nitrogen. When administered to the acutely ill asthmatic, heliox can decrease airway resistance by restoring laminar flow in obstructed airways where flow has become more turbulent. Work of breathing is decreased, and the patient is less likely to fatigue. However, there is no direct curative action of heliox, and its effect occurs only while in use. It may also be used to drive a small-volume nebulizer to deliver albuterol, but this requires a specialized closed delivery system. Current data do not support the routine use of heliox in the emergency department.

Heliox may be a useful bridge therapy for the severely ill patient in the intensive care unit who is tiring. It becomes less effective if concentrations lower than 70% helium are used, making it less useful in significantly hypoxic patients.

Montelukast administered intravenously or orally as an adjunct treatment for status asthmaticus, in addition to standard treatment with a SABA and systemic corticosteroids, has not proven useful in improving symptoms, pulmonary function, or need for hospital admission in children.[164] The routine use of montelukast for treatment of status asthmaticus cannot be recommended at this time.

Failure to clear symptoms (particularly dyspnea, chest wall retractions, or use of accessory muscles); persistent hypoxemia ($O_2$ saturation < 92% while breathing room air); and improve air exchange and (if measured) PEFR to above 40% to 50% predicted are some indicators for hospital admission.

## Hospital Management of Asthma

Status asthmaticus, or acute severe asthma that is resistant to appropriate outpatient therapy, is a significant medical emergency that requires prompt, systematic, and aggressive management in the hospital. The initiation of early appropriate therapy shortens hospitalization and reduces complications for the vast majority of acutely ill patients. In spite of improved efforts at diagnosing and treating asthma, status asthmaticus continues to be the one of the most common discharge diagnoses from children's hospitals, accounting for 15%–30% of all admissions. The increase in hospitalizations for asthma reported in all age groups during the last decade now appears to have slowed.

## General Treatment

A physician, nurse, respiratory therapist, and consultant pulmonologist team should manage the child with status asthmaticus in a closely monitored inpatient unit. Although the management of each child with status asthmaticus must be individualized, certain general principles apply to all patients with this diagnosis.

Humidified oxygen should be administered (2–3 L/min by nasal cannula or 30% fraction of inspired oxygen [$F_{IO_2}$] by facemask) to maintain oxygen saturation in arterial blood ($Sa_{O_2}$) greater than 93% at sea level. The appropriate use of oxygen helps relieve dyspnea, aids in bronchodilatation, supports the myocardium, and helps prevent arrhythmias. Failure of improvement in hypoxemia with modest amounts of oxygen suggests either severe airway obstruction and impending respiratory failure or a complicating factor, such as pneumonia, atelectasis, or another diagnosis besides asthma. IV infusion of fluids is generally not required unless the patient is unable to take or tolerate oral fluids or requires IV access for steroids or antimicrobials (if needed for concomitant infection). PFTs ($FEV_1$ or PEFR) may be performed at the bedside if the child can cooperate; however, most acutely ill children cannot do acceptable spirometry. Pulse oximetry (or arterial or capillary blood gas if hypercarbia or acidosis is suspected) should be measured as soon as possible and repeated as the patient's condition warrants. Although not needed on all asthmatics, a chest radiograph provides information on other pulmonary problems that might complicate management in patients who do not respond rapidly to treatment (e.g., pneumonia, atelectasis, pneumomediastinum, or pneumothorax).

Details about the acute illness (its duration, progression, manifestations, and initiating factors), information on the duration and the reports of previous acute episodes, and level of functional morbidity and medication use at the patient's stable baseline should be noted. The patient's medication (including the names, dosages, and exact time of all medications administered within 24 hours) and any systemic corticosteroid drugs administered within 12 months should be documented. These data will be useful in constructing a treatment plan upon hospital discharge.

On physical examination, the general appearance and level of activity, respiratory effort, presence or absence of wheezing, tachycardia, tachypnea, air exchange, adventitious breath sounds, use of accessory muscles, dyspnea, and color are important clinical parameters that provide information about pulmonary dysfunction.

Although the number of pharmacologic agents for treatment of status asthmaticus is relatively limited, management strategies are inconsistent among and within institutions (see Table 45.4A and B). Evidence-based practice is often replaced by physician personal experience and preference. Elimination of treatment that adds risk and cost but does not improve quality of care should be a primary goal. Status asthmaticus readily lends itself to treatment by the standardized clinical pathway, and several published studies have demonstrated shortened hospital stays using such care paths.[165] Administration of oral corticosteroids within 75 minutes of arriving in the emergency department decreases the need for admission.[166]

### Table 45.4B

### Adjunct Medications for Severe Episodes

| Medication | Child (<12 years) | Adolescent |
|---|---|---|
| **MAGNESIUM SULFATE** | | |
| Intravenous (IV) | Bolus: 50 mg/kg per dose (25–75 mg/kg per dose; max 2 g)<br>Administer over 20 min | |
| **SYSTEMIC (INJECTED) $\beta_2$ AGONISTS** | | |
| **Epinephrine** | | |
| Intramuscular (IM)<br>1 : 1,000<br>(1 mg/mL) | 0.01 mg/kg (max 0.3–0.5 mg) every 20 min for 3 doses | 0.3–0.5 mg every 20 min for 3 doses |
| **Terbutaline** | | |
| Intravenous (IV) | 0.01 mg/kg bolus (max 0.4 mg) over 10 min | 0.01 mg/kg bolus (max 0.75 mg) over 10 min |
| Subcutaneous (SQ) | 0.01 mg/kg (max 0.25 mg) | 0.01 mg/kg (max 0.25 mg) |
| (1 mg/mL) | May repeat every 15 min for 3 doses | May repeat every 15 min for 3 doses |

No advantage has been found for higher-dose corticosteroids in severe asthma exacerbations.[1]

There is no advantage for intravenous administration over oral therapy, provided gastrointestinal function is intact.

Therapy following a hospitalization or emergency department visit is typically 5 days but may last from 3 to 10 days. Studies indicate that there is no need to taper the systemic corticosteroid dose when given up to 10 days. Dosages in excess of 1 mg/kg of prednisone or prednisolone have been associated with adverse behavioral effects in children, whereas 1 mg/kg provides equivalent pulmonary benefit without the adverse effects in most cases.

Medical management of the hospitalized asthmatic should include aggressive use of inhaled bronchodilators, most commonly albuterol, and systemic corticosteroids. The frequency of treatment should be guided by the patient's condition. In most inpatient, nonintensive care unit settings, inhalations may be administered as frequently as every 1–2 hours. In some settings, where close monitoring is available outside the intensive care unit, consideration may be given to administering albuterol continuously (10–15 mg/hour) for short time periods (1–4 hours). Treatments should be administered only if the patient's respiratory status indicates need; studies have shown that such assessment-driven administration of SABAs is as effective as scheduled treatments. Moreover, patients who are treated on an "as-needed" basis are likely to receive fewer treatments at less cost. If the patient cannot tolerate oral therapy, IV administration of corticosteroids should be ordered. Methylprednisolone, 1–2 mg/kg (maximum 125 mg) may be given daily. Failure to improve significantly after a maximum of 12 hours of such therapy should prompt a search for other complicating factors and impending respiratory failure, and indicates a need for more aggressive monitoring and treatment. If at any time the patient's condition deteriorates, consideration should be given to administering immediate intensified treatment, such as SQ epinephrine (0.01 mL/kg, maximum 0.3 mL), terbutaline, or 500 μg aerosolized ipratropium with 5 mg albuterol. If a favorable response is observed, the aerosol treatment may be repeated every 20 minutes over the next hour. Patients who fail to sustain improvement after such treatment should be transferred to the intensive care unit.

The asthmatic child requiring intensive care should be monitored carefully for the development of respiratory failure. Physical findings such as severe dyspnea, inability to lie flat, poor air exchange, severe wheezing, and use of accessory muscles of respiration are all indicators of impending respiratory failure. Continuous cardiorespiratory monitoring and pulse oximetry with intermittent determination of arterial or venous blood gas measurement to assess oxygenation, ventilation, serum electrolyte, and acid-base status are necessary. Treatment should consist of continuously nebulized albuterol (0.15 mg/kg per hour, maximum 15 mg), ipratropium 500 μg nebulized every 4–6 hours, and methylprednisolone 1–2 mg/kg (maximum 125 mg) every 24 hours.

Serum potassium concentration should also be closely monitored, because frequent SABA administration may cause hypokalemia.

A few studies suggest that IV aminophylline may result in the more rapid resolution of symptoms compared with placebo, although overall intensive care length of stay was not affected. For the patient who fails to respond, treatment with a bolus and possible continuous IV infusion of a β-adrenergic agonist (e.g., terbutaline) can be considered (IV albuterol [salbutamol] is not available in the United States). Delivery of the medication via the circulation may provide relief of bronchospasm in areas not receiving medication via the inhaled route due to severe airway obstruction. However, most studies do not report significant improvement compared with use of continuous nebulized SABA treatment. The starting dose of terbutaline is 5 μg/kg, followed by a continuous infusion of 0.4 μg/kg per minute. The dose is increased by 0.2 μg/kg per minute to a maximum dose of 12–16 μg/kg per minute, although higher doses have been used. Baseline and twice-daily cardiac isoenzymes and continuous electrocardiograms must be monitored because myocardial toxicity has been reported. Although every effort should be made to avoid intubation and mechanical ventilation, a small percentage of severely ill patients (<10%) may require invasive ventilatory support. It is difficult to mechanically ventilate an asthmatic, and the complication rate may exceed 30%. Indications for intubation have become more conservative and should be reserved for patients who have apnea, unstable vital signs, impaired level of consciousness, severe acidosis, extreme fatigue, and failure of noninvasive ventilation. A trial of noninvasive ventilation using continuous positive airway pressure (CPAP) or bilevel positive airway pressure (Bi-Pap) may be successful in some patients. Low levels of $H_2O$ pressure (5–10 cm) may be helpful in reducing work of breathing and improving oxygenation over a several-hour trial. Some patients become anxious using the tight-fitting facemask necessary for effective CPAP and may require a modest dose of a short-acting benzodiazepine to comply with treatment. Risks include gastric distention, vomiting, aspiration, or air leak.

A skilled intensivist or anesthesiologist using rapid-sequence induction anesthesia should perform intubation when necessary. It is important to make certain the patient is adequately hydrated prior to intubation and not given excessive positive pressure bag ventilation immediately after. Asthmatic patients are at risk for significant hypotension following intubation because of extreme hyperventilation leading to auto-PEEP, which impedes systemic venous return; this can be further exacerbated by volume depletion and application of aggressive positive pressure ventilation. Continuous sedation is usually required during mechanical ventilation. High peak inspiratory pressures are often noted, and efforts should be made to reduce them to less than 45 mm Hg. Use of selective hypoventilation (permissive hypercapnia) must be practiced, and attempts to immediately normalize ventilation should be avoided. Relief of hypoxemia, respiratory distress, and muscle fatigue are the goals. Volume ventilation with a square wave form and the lowest volume and flow to minimize peak pressure and volume damage while maximizing expiratory time is usually recommended, but there are reports of successful use of pressure-controlled ventilation. Relatively low respiratory rates (8–10/min), low tidal volumes (6–8 mL/kg), and prolonged expiratory time should be tried as ventilator strategies. Decreasing the minute ventilation can maximize expiratory time; this can be best accomplished by using a lower respiratory rate or tidal volume. Shortening the inspiratory time by increasing the inspiratory flow rate can work, but it may be less effective and may contribute to airway injury caused by high shear forces. As long as metabolic acidosis is not present, a pH as low as 7.2 can be tolerated. IV infusion of sodium bicarbonate for more profound acidosis is controversial and generally not recommended. All medications should be continued while the patient is mechanically ventilated. Delivery of aerosolized bronchodilators through the endotracheal tube using an MDI and spacer device should be continued as well. Extubation should be considered and attempted using standard criteria, such as normoxemia with an $FIO_2$ of less than 0.40, spontaneous tidal volume greater than 5 mL/kg, vital capacity greater than 15 mL/kg, maximum inspiratory pressure (MIP) greater than 25 cm $H_2O$, and the ability to protect the airway and handle secretions. Most patients can be successfully weaned and extubated within 72 hours.

Several other therapies for the severely ill asthmatic have been tried, but they are still considered unproven or experimental. IV $MgSO_4$ should be tried, particularly if not administered previously. Heliox has been reported to decrease pulsus paradoxus and improve air flow in acutely ill, nonintubated asthmatic children, and can also be administered during mechanical ventilation. However, this therapy is unproven, and the less-dense gas alters ventilator function, requiring careful ventilator adjustment and a knowledgeable respiratory therapist. Administration of inhaled general anesthetic agents (e.g., enflurane and sevoflurane, which are bronchodilators) has also been used with some success; however, reports are anecdotal, and no controlled trials have been conducted. These agents are also myocardial irritants and may precipitate serious arrhythmias in the acidotic, hypoxemic asthmatic. Ketamine infusions can be considered for sedation of the intubated patient, since the drug also has some bronchodilator properties. However, the adverse psychoactive effects of ketamine can be problematic in older children and may only be partially obviated by the concomitant administration of a benzodiazepine.

Of note, most patients who develop life-threatening asthma and respiratory failure do so outside the hospital or shortly after arriving at a medical facility. Most asthma deaths occur prior to reaching an intensive care unit and institution of successful airway management. Once successfully stabilized in an intensive care unit that is familiar with the management of acute severe asthma, patients who have not experienced respiratory arrest or prolonged hypoxia are likely to survive intact.

# Severe Asthma

*Andrew Bush MB BS(Hons), MA, MD, FRCP, FRCPCH, FERS* [a], *Louise Fleming MB ChB, MRCP, MRCPCH, MD*

Most children with asthma can be easily treated with low-dose inhaled corticosteroids (ICS) if these are regularly and correctly administered. Hence, refractory asthma probably accounts for less than 5% of all pediatric asthma.[1] It may be becoming less common over time, possibly because of more effective modern treatments and likely also improved management.[2] However, this group accounts for an enormous amount of morbidity and health care costs, and even mortality, and so although rare, it is important. Here, our practice approach to the child with apparent refractory asthma is described. Severe preschool wheeze is not discussed here.

## Overarching Principles

The cardinal sin in asthma management is to continue to escalate asthma therapy in a child who is not responding, without asking, "Why is simple prescribed treatment not working?" We know that most children with asthma will respond very well to low-dose ICS, sometimes also requiring a second controller, such as long-acting beta-2 agonists (LABA), or a leukotriene receptor antagonist (LTRA).[3] So, faced with the child with apparently refractory asthma, the pediatrician should not reach again for the prescription pad, but go through a rigorous protocol to determine what it is about this child and his or her asthma that means the anticipated response is not happening. The overall aim of the protocols discussed below is to determine whether the individual child is truly a candidate for “beyond guidelines” therapy or can, in fact, be managed with standard approaches.

## Definitions

The conventional developed world definition of severe asthma[4,5] is that the patient requires treatment with guideline-suggested medications for GINA (Global Initiative for Asthma) steps 4–5 asthma (high-dose ICS, conventionally 800 μg/day beclomethasone equivalent for 5- to12-year-olds; >1600 μg for children aged >12 years; and LABA or leukotriene modifier/theophylline) for the previous year; or systemic corticosteroids (CS) for ≥50% of the previous year to prevent it from becoming “uncontrolled”; or which remains “uncontrolled” despite this therapy; or controlled asthma that worsens on tapering of these high doses of ICS or systemic CS (or additional biologics). Uncontrolled asthma is currently defined as one or more or of:

1. *Poor symptom control:* Asthma Control Questionnaire (ACQ) consistently >1.5, Asthma Control Test (ACT) <20 (or “not well controlled” by NAEPP [National Asthma Education and Prevention Program]/GINA guidelines).
2. *Frequent severe exacerbations:* two or more bursts of systemic CS (>3 days each) in the previous year.
3. *Serious exacerbations:* at least one hospitalization, intensive care unit (ICU) stay or mechanical ventilation in the previous year. However, objective evidence of the severity of the attack should be obtained. In theory, the treatment of an asthma attack is based on objective evidence of current severe airflow obstruction. In practice, especially in emergency situations dealt with by the inexperienced, the previous history may unduly influence practice. It is essential to determine what (if any) objective assessments were carried out before instituting treatment, and whether in fact the child was overtreated because of a “severe asthma” label. One child under our care was actually started on intravenous albuterol despite being fully saturated on

room air! In fact she had dysfunctional breathing and vocal cord dysfunction.

4. *Airflow limitation:* after withholding bronchodilators for 4 hours (short acting) or 12 hours (long acting) first second forced expired volume ($FEV_1$) <80% predicted (in the face of reduced $FEV_1$/forced vital capacity (FVC) defined as less than the lower limit of normal); however, it should be noted that normal spirometry does not exclude severe asthma in children[6]; unlike in adults, spirometry is poorly discriminatory between different levels of asthma severity and is not a good end-point in pediatric asthma trials.[7–9]
5. *Fixed airflow limitation:* $FEV_1$ <80% predicted (in the face of reduced $FEV_1$/FVC defined as less than the lower limit of normal) despite a trial of systemic steroids and acute administration of short-acting beta-2 agonists (SABA).
6. *Disconnect symptoms:* perhaps strictly the child presenting with a multitude of symptoms with no objective evidence of uncontrolled disease may belong in a separate disease category, and certainly is not placed conventionally in severe asthma guidelines, but the means of addressing this scenario are so very similar that this is pragmatically justified. The reverse scenario, the underreporting of symptoms, is also considered below.

Inherent in this definition is that basic management, including adherence, has been optimized, a process described in more detail below.

It can be argued that the level of ICS dose has been set too high. The Best Add-on Therapy Giving Effective Responses (BADGER) study[10] shows that for most children, there is no benefit from increasing ICS above 100 μg bid (200 μg beclomethasone); a child not responding to this level of ICS plus one additional controller medication definitely merits a careful review.

Furthermore, the WHO has defined three types of severe asthma[11]:

1. *Untreated:* due to undiagnosed asthma or the unavailability

of therapy (this being the most common worldwide)
2. *Difficult-to-treat:* due to adherence issues, inappropriate or incorrect use of medicines, environmental triggers or comorbidity
3. *Treatment-resistant:* this includes asthma for which control is not achieved despite the highest level of recommended treatment, or asthma that is controlled only with the highest level of recommended treatment.

Clearly, each of these categories merits a different response. The lack of availability of therapy needs to be tackled at a public health level, ensuring that each and every child with asthma has access to the basics; namely, inhaled beclomethasone and albuterol, prednisolone, and a plastic bottle spacer. Biologicals have no place in this setting. For those with treatment-resistant severe asthma, on the other hand, deploying novel therapeutics may be transforming.

An overlapping approach, which is also a useful conceptual framework, is to define risk by considering domains of asthma severity. Conventionally, these are:

1. Level of prescribed treatment
2. Level of baseline asthma control over the previous month
3. Level of underlying airway eosinophilia (in adults, possibly children, also)
4. Burden and nature of exacerbations over the last 6–12 months
5. Risk of future complications, including the failure of normal airway growth (for which there is increasing evidence); the risk of either or both of future loss of control and exacerbations; the risk of medication side effects.

It could certainly be argued that the conventional definition fails to focus on domains that the patients and families find important, such as quality of life, the impact on school attendance, and the time away from work for the carers. Perhaps what we mean by "control" needs a broader perspective. Furthermore, the recent UK review of asthma deaths[12] suggests that we need to refocus our definitions: around 60% of those who died from asthma were classified as “mild to moderate.” Since it is difficult to imagine a more severe outcome than dying, it is obvious that our definitions need to be reconsidered. These patients could be placed in the difficult to treat category, but patient factors (Box 46.1) need to be added to the conventional definitions of risk.

**Box 46.1**

### Lessons From the UK NRAD—What Makes a Patient a High Risk for Death From Asthma?

- A single severe exacerbation
- Recent discharge from hospital after an acute asthma attack
- Use of hospital urgent care facilities in the previous year
- Utilization of more than six canisters of SABA/year
- Failure to attend follow-up appointments

*SABA*, Short-acting beta-2 agonists.

This underscores that difficult-to-treat asthma can be just as serious as treatment-resistant severe asthma, and merits a response that is just as focused if we are to impact deaths from asthma.

## A New Approach: Airways Disease Deconstructed and Placed in Context

A new framework has been suggested for the assessment of airway disease.[13] The problem is multicomponent, and is best considered under three headings: airway disease itself, extrapulmonary disease (comorbidities), and environmental/lifestyle factors. The initial assessment of problematic severe asthma focuses on the last two, because generally, the first is easily managed (above), and therefore the focus is on potential confounding factors. If the problem remains, the nature of the airway disease is ascertained invasively. The protocol used is discussed in more detail below.

# Initial Evaluation: Problematic Severe Asthma

Problematic severe asthma is the umbrella term when a referral of a child meeting one or more of the above criteria is received in a specialist respiratory center (Box 46.2). A full history and physical examination is the essential first step. The nature of the symptoms should be determined. The word "wheeze" is used very imprecisely, often being used to describe many nonspecific respiratory sounds, and even stridor[14–18]; until a physician has heard wheeze with a stethoscope, it should be considered as "possible."[19] Most children who have a cough as their sole symptom (particularly an isolated dry cough) do not have a disease.[20]

**Box 46.2**

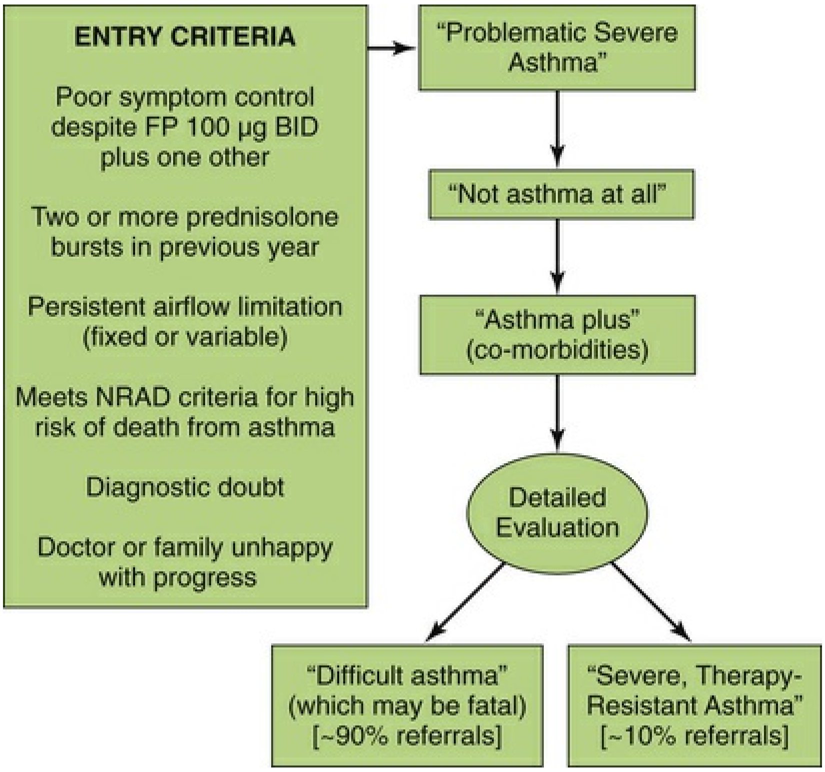
## What May Lie Under the "Problematic Severe Asthma" Umbrella?

1. *Not asthma at all:* the diagnosis is wrong.
2. *Asthma plus:* there are associated comorbidities that need to be addressed.
3. *Difficult asthma:* accounts for about 90% of those in whom the first two categories have been excluded. This comprises children who need to get the basic steps of asthma management correct; the percentage of difficult asthma compared with severe, therapy-resistant asthma has risen over the years as we have become more expert in assessing these children, in particular adherence issues.
4. *Severe, therapy-resistant asthma:* these children appear to have ongoing problems with asthma despite the optimization of all basic steps of asthma management; such children are candidates for "beyond guidelines" therapy, and account for around 10% of referrals.

Physiological tests are mandatory at this point. It should be noted that spirometry is often normal in children with severe asthma, which is different from adults. Testing for airway hyperresponsiveness is not routine, and may be risky in these severe asthma patients. In any event, the relationship between $PC_{20}$ to methacholine and asthma severity is poor. The most common use of this test is in a child with normal spirometry who is reporting a multiplicity of symptoms; a normal methacholine challenge excludes asthma as a cause of these symptoms. Airflow obstruction, which changes over time or with treatment, must be documented and consideration given to determining whether the child is atopic and has airway eosinophilia. Nonatopic asthma does occur in childhood, but is uncommon, and if skin prick tests or specific immunoglobulin E (IgE) are negative, the diagnosis should be reevaluated. Blood eosinophilia may give a guide to airway eosinophilia, but an elevation may be due to other atopic disease, for example eczema. Fractional exhaled nitric oxide (FeNO) measured at a flow rate of 50 mL/s ($FeNO_{50}$) has been used as a diagnostic tool for asthma, but it should be noted that a low $FeNO_{50}$ does not exclude asthma, and elevation is seen in atopic children with no respiratory disease.[21] An induced sputum cytospin will give more direct evidence of airway eosinophilia, but is not available in most centers. Although evidence of airway inflammation is not a mandatory diagnostic test for asthma, and a child already on treatment with ICS may be inflammation free, the absence of any evidence of airway inflammation in a child supposedly symptomatic with asthma should prompt a diagnostic review. Finally, the diagnostic process should not end at this stage; the possibility of a wrong diagnosis should be at the forefront throughout, and further testing should be considered in the presence of a surprising finding, such as airway neutrophilia (see later).

It may be thought inappropriate to be discussing basic asthma diagnosis in a chapter on severe asthma, but wrong diagnosis, often due to failure to perform objective tests, is an all-too-common reason why treatment fails.

The suggested flow chart for evaluating children with asthma who are not responsive to treatment is shown in Fig. 46.1. The low level of ICS used to trigger evaluation may raise the specter of tertiary services being drowned in referrals, but this is not necessarily the case. Furthermore, this framework can be modified and adapted to all health care settings. Given (1) the plateau of the ICS dose response curve being low[10]; and (2) the generally poor response to LTRAs,[22] time should not be wasted by increasing ICS doses ever higher, and adding in more and more different controllers. Rather, one should ask, "why is this child not responding to low-dose ICS and one controller?" Simple checks can easily be done in primary care. A diagnostic review is mandatory: are the symptoms in fact due to no more than repeated viral upper respiratory infections? Is the child using the medication delivery device correctly? Are there adverse environmental factors, such as tobacco smoke exposure (passive or active)? Nonadherence can easily be checked by examining prescription records. In one study, only one in six children was having enough prescriptions filled to take their prophylactic medication.[23] Even patients referred to us with apparently severe asthma collect less than half of their prescriptions.[24] Of course, picking up a prescription does not mean the medication has actually reached the lower airways (below)!



ENTRY CRITERIA
Poor symptom control despite FP 100 µg BID plus one other
Two or more prednisolone bursts in previous year
Persistent airflow limitation (fixed or variable)
Meets NRAD criteria for high risk of death from asthma
Diagnostic doubt
Doctor or family unhappy with progress
"Problematic Severe Asthma"
"Not asthma at all"
"Asthma plus" (co-morbidities)
Detailed Evaluation
"Difficult asthma" (which may be fatal) [~90% referrals]
"Severe, Therapy-Resistant Asthma" [~10% referrals]

**FIG. 46.1** Modified diagnostic protocol for investigation

of severe asthma. *BID*, Twice daily; *NRAD*, National Review of Asthma Deaths.

Referral may also be indicated even if the primary pediatrician is confident that the child has difficult asthma, but repeated interventions have failed to reduce the risk factors for asthma death. The possibility of diagnostic error still remains, and the use of a multifaceted intervention may be able to reduce risk.[25,26]

## Problematic Severe Asthma: Not Asthma at All

The differential diagnosis of problematic severe asthma is summarized in Table 46.1. There is a wide differential diagnosis of asthma, the nature of which varies across the world. Important red flags, which should prompt investigation, include neonatal onset of symptoms, chronic productive cough for more than 8 weeks continuously (not recurrent acute cough with complete resolution between episodes), and evidence of systemic disease. The nonatopic child with apparently severe asthma should always be carefully reassessed, and alternative diagnoses sought. We do not routinely perform a chest high-resolution computed tomography (HRCT) in all children referred with problematic severe asthma, reserving this investigation for those with atypical features; there is no evidence in children to set against this selective approach. Specifically, HRCT cannot differentiate obliterative bronchiolitis from asthma,[27] and severe asthma; HRCT phenotypes such as those known in adults[28,29] have not been described in children. In general, testing should be focused to eliminate specific conditions, rather than taking a scattergun approach.

**Table 46.1**

**Differential Diagnoses of Severe Asthma**

| Class of Diagnosis | Examples |
|---|---|
| Defects of host defense | Cystic fibrosis, primary ciliary dyskinesia, persistent bacterial bronchitis<br>The effects of high-dose inhaled steroids should be considered |

| | |
|---|---|
| Systemic immunodeficiency | Any, including B-cell and T-cell dysfunction |
| Intraluminal bronchial obstruction | Foreign body, carcinoid, other tumor |
| Intramural bronchial obstruction | Bronchomalacia, complete cartilage rings, intramural tumor<br>In low- and middle-income countries, bronchiectasis due to severe infection in an otherwise healthy child is particularly important |
| Extraluminal bronchial obstruction | Vascular ring, pulmonary artery sling, congenital lung cyst, enlarged lymph nodes due to tumor or tuberculosis, other mediastinal masses<br>In low- and middle-income countries, tuberculosis is a particularly important cause |
| Direct aspiration | Bulbar or pseudobulbar palsy; laryngeal cleft; laryngeal neuropathy or myopathy |
| Aspiration by direct contamination | H-type fistula, which may not present until adult life |
| Aspiration secondary to reflux | Any cause of gastro-esophageal reflux, including hiatus hernia and esophageal dysmotility (e.g., achalasia or after neonatal repair of tracheoesophageal fistula) |
| Complications of prematurity | Bronchomalacia, stricture secondary to intubation, vocal cord palsy secondary to surgery for patent arterial duct |
| Congenital heart disease | Bronchial compression from enlarged cardiac chambers or great vessels; pulmonary edema |
| Interstitial lung disease | Any not presenting with neonatal respiratory failure |
| Dysfunctional breathing | Vocal cord dysfunction, hyperventilation syndromes (usually a comorbidity in a known asthmatic, but may present in isolation) |

## Airway Disease in Context: Asthma Plus (Extrapulmonary Comorbidities)

A so-called comorbidity may (1) worsen asthma; (2) be a coincidental fellow traveler; (3) obscure the assessment of asthma; or (4) be an example of Berkson fallacy. This last is a special example of selection bias. This occurs when, for example, the combination of exposure and disease under study increases the risk of hospital admission, thus leading to a higher exposure rate among the hospital cases than the hospital controls; and is a frequent cause of manuscripts being rejected! The clinical significance of the first three categories is obviously different: (1) and (3) are important as “treatable traits,” whereas (2) is not. Furthermore, it may be easy to identify a treatable trait, such as obesity, but in practice, treatment may be difficult. The ethics of escalating treatment with expensive and potentially hazardous drugs under these circumstances are debatable.

## Obesity

The relationships between asthma and obesity are difficult to assess, and too many studies merely report associations that are difficult to disentangle. Obesity may cause breathlessness and "wheeze" especially on exercise without evidence of asthma, leading to inappropriate treatment. Obesity may be associated with a pauci-inflammatory form of asthma, at least in adults, although it is sometimes unclear whether this is true asthma[30]; asthma with raised sputum interleukin (IL)-5 and airway wall eosinophilia[31]; or steroid resistance.[32] Obesity is a proinflammatory state,[33] as is obstructive sleep apnea (see later).[34] Asthma (via reduced exercise performance) and its treatment (prednisolone bursts or long-term therapy) may cause or contribute to obesity. Hence, particular care is necessary before escalating therapy for "asthma" in the obese child with respiratory symptoms; an exercise-induced asthma test may be enlightening. A normal methacholine challenge also may be useful to exclude asthma as a cause of symptoms. In asthmatic adults, bariatric surgery improved distal airway function (impulse oscillometry, systemic inflammation [serum high sensitivity C-reactive protein, adiponectin, and leptin] and airway inflammation [decrease in mast cell numbers]).[35] In summary, obesity hits all three mechanisms of comorbidity: it may worsen asthma, obscure the assessment of asthma, and be a fellow traveler. Weight reduction is always beneficial in the obese child, but is often difficult to achieve, and its contribution to the clinical picture must be assessed on an individual basis.

## Gastroesophageal Reflux

The relationship between respiratory disease and gastroesophageal reflux is also complex. Reflux can cause symptoms either by direct contamination of the lower airway, or indirectly by an esophago-bronchial reflex[36–38]; respiratory disease may lead to abnormal pleural pressure swings or altered configuration of the diaphragm —the latter reducing the efficiency of the lower esophageal sphincter; and reflux may be present but noncontributory. However, irrespective of any symptoms suggestive of reflux, therapy with, for example, a proton pump inhibitor does not improve severe asthma,[39–41] which is certainly our experience. This does not exclude the possibility that nonacid reflux may be contributory, although there is also no positive evidence for this. So, reflux is a potentially treatable trait, and the symptoms of reflux may mimic or coexist with asthma, and thus complicate the assessment of asthma.

## Food Allergy

Atopy is almost inevitable in severe pediatric asthma, and indeed "non-atopic asthma" merits the most careful diagnostic review. However, food allergy is reported more commonly than expected in severe asthma.[42,43] Whether food allergy is causative of the problem or a marker is unclear; certainly anaphylaxis enters the differential diagnosis of acute, severe asthma, and should always be considered because it is treatable. Exercise-induced anaphylaxis must be differentiated from other causes of breathlessness on exercise (see later) by a careful history. Food allergy should always be documented with a double-blind challenge unless there is overwhelming evidence for the diagnosis if exclusion diets are proposed; however, blind dietary exclusions are frequently tried and inevitably useless in our experience.

## Rhinosinusitis

Upper airway disease worsens the quality of life, and should be treated on its own merits in any context.[44–46] There is increasing evidence that treating rhinosinusitis may be beneficial at least in mild-to-moderate asthma.[47–49] The mechanisms of any benefit remain conjectural.[50] Upper airway symptoms may complicate the assessment of asthma; for example, causing night waking, which may be mistaken for uncontrolled asthma. In our series, significant rhinosinusitis is unusual in severe asthma, but in the **U-BIOPRED** (**U**nbiased **BIO**markers for the **PRED**iction of respiratory disease outcomes) cohort,[51] two-thirds had a diagnosis of allergic rhinitis. An assessment of the respiratory tract is incomplete without consideration of the nose.

## Sleep Disordered Breathing

There is an increasing amount of literature on asthma and obstructive sleep apnea (OSA).[52] Although the literature reports associations in at least mild-to-moderate asthma, in our patients, OSA is very rare in severe asthma, except in the presence of concomitant obesity. We do not routinely perform polysomnography on children with severe asthma who are not obese. OSA has been reported to cause sputum neutrophilia rather than eosinophilia in one study[53]; this inflammatory pattern rarely, if ever, occurs in true severe, therapy-resistant asthma, and if seen, it should prompt a diagnostic reevaluation. As with rhinosinusitis, disturbed sleep due to OSA may be misdiagnosed as uncontrolled asthma.

## Syndromes of Vocal Cord Dysfunction and Other Functional Breathing Issues

Dysfunctional breathing is common in some,[54] but not all,[55] asthma cohorts. The symptoms are easily confused with uncontrolled asthma, leading to inappropriate treatment escalation. There is much less work in children than in adults.[56–58] Of the children investigated in our protocol, 15% had evidence of dysfunctional breathing,[24] including hyperventilation and vocal cord dysfunction. Clues include the absence of symptoms at night, and often stridor rather than expiratory noises. Spirometry is frequently not reproducible, and there may be attenuation of the inspiratory curve during attacks.

Breathlessness on exercise may be challenging to evaluate, with a wide differential diagnosis (Box 46.3). Exercise induced laryngeal dysfunction (EILO) may be particularly challenging to diagnose. There are important points on the history; exercise-induced bronchoconstriction is common in asthma, and is characterized by symptoms usually more than 5 minutes after exercise, a feeling of difficulty breathing out, and a good response to pretreatment with SABA. By contrast, EILO (which often complicates asthma) is characterized by symptoms during exercise in which breathing in, not out, is difficult, and is accompanied by an inspiratory noise, which are not helped by asthma medications. A video during an attack of exercise-induced breathlessness may be very informative; in older children, direct laryngoscopy during an exercise test enables direct demonstration of the problem.

**Box 46.3**

### Differential Diagnosis of Exercise-Induced Breathlessness

- Exercise-induced bronchoconstriction
- VCDEILO
- Deconditioning (which may have resulted from asthma)
- Obesity (which may also be the consequence of asthma and its treatment)
- Exercise-induced anaphylaxis (a detailed history of food intake prior to exercise is essential)
- Pulmonary hypertension (consider especially in children who "faint" during exercise)

*EILO,* Exercise-induced laryngeal obstruction; *VCD,* vocal cord dysfunction.

A large community-based questionnaire study in 3838 adolescents reported a prevalence of exercise-induced bronchoconstriction of 19.2%, with 5.7% reporting EILO.[59] A sub-sample (*n* = 99 with exercise dyspnea; *n* = 47 without) underwent standard treadmill exercise-induced asthma and EILO (direct laryngoscopy) tests. A total of 39.8% had exercise-induced bronchoconstriction, 6% EILO, and 4.8% had both on objective testing. Thus, nearly 50% had neither condition, but many were being prescribed treatment for asthma. The cause of breathlessness in this group could not be determined, but they were not the obese. This important manuscript underscores the importance of objective assessment of breathlessness on exercise.

If dysfunctional breathing is suspected, an experienced respiratory physiotherapist should be asked to assess the breathing pattern. Treatment with breathing exercises may be helpful, although currently there is no randomized, controlled trial evidence of benefit.[60] The services of a sports psychologist may also be useful.

EILO also may be related to laryngomalacia in the newborn period.[61] A total of 20/23 (87%) of infants hospitalized for laryngomalacia (half with an unconfirmed clinical diagnosis) were followed up at a mean age of 11 years and compared to a group of matched controls. A respiratory symptom questionnaire, and spirometry and laryngoscopy at rest and during exercise were performed, and the exercise laryngoscopy findings scored blind. EILO was found on exercise in 14/20 (compared with 2/20 controls) and at rest in 9 (none in controls). Thus a neonatal history is an important part of the evaluation of suspected EILO, and laryngomalacia in infancy may be a less benign condition than previously thought.

A further problem is that the perception of dyspnea has been little studied in severe pediatric asthma,[62] but in adults, severe asthmatics do not become as dyspneic as mild during bronchoconstriction.[63] The possibility of poor symptom perception as a cause of an apparent sudden catastrophic deterioration should be borne in mind.

## Airway Disease in Context: Environmental/Lifestyle (Difficult Asthma)

When, as far as possible, a correct diagnosis has been ensured, and comorbidities dealt with, a detailed nurse-led assessment is performed (Table 46.2). We evaluate allergic sensitization by both skin prick tests (SPTs) and sIgE tests, because there is imperfect concordance (76%–83%) between them.[64,65] Because it is so labor intensive, we are increasingly using electronic monitoring to screen out the nonadherent before going on to a detailed work-up, which is led by the specialist asthma nurse and often involves the clinical psychologist and respiratory physiotherapist. This includes both a hospital outpatient visit and a community assessment, which includes a home visit and at least a telephone call to the school by the nurse specialist.[24]

## Table 46.2

### Nurse-Led Assessments in Problematic Severe Asthma (Hospital, Home, and School Visit)

| **Issue to Be Addressed** | **Tests Performed** |
|---|---|
| Symptom pattern | ▪ Asthma control test (≥12 years), or Childhood Asthma Control Test (6–11 years), prednisone bursts, unscheduled visits<br>▪ Obtain records of objective assessments of the severity of asthma attacks<br>▪ Asthma plan reviewed and updated |
| Psychosocial factors | ▪ Questionnaires (PI-ED; we also use the Hospital Anxiety and Depression Scale [HADS] to assess the main care giver); this is readdressed during the home visit, and it is after this that most issues come to light |
| Lung function | ▪ Spirometry before and after bronchodilator |
| Allergic sensitization<br>▪ Aeroallergens<br>▪ Food allergens<br>▪ Fungi | ▪ Skin prick tests, specific IgE<br>▪ grass and tree pollen, house dust mite, cockroach, cat and dog, and any others suggested by the clinical history<br>▪ peanut, milk, egg and any others suggested by the clinical history<br>▪ See Box 46.7 |
| Airway inflammation | ▪ FeNO50 (multiple flow rates are not routinely used)<br>▪ Induced sputum with hypertonic saline if FEV1 >70% predicted |
| Tobacco exposure | ▪ Urine or salivary cotinine<br>▪ Exhaled CO for active smoking |
| Medication adherence | ▪ Serum prednisolone and theophylline levels if prescribed<br>▪ Serum ICS levels if available<br>▪ Prescription uptake<br>▪ Electronic monitoring |
| Home visit | ▪ Environmental exposures, particularly pets and tobacco smoke<br>▪ Psychosocial issues reassessed<br>▪ Asthma education and plan reassessed<br>▪ Medication availability and accessibility addressed |
| School visit or contact by telephone | ▪ School attendance<br>▪ School assessment of level of disability<br>▪ School concerns about any psychosocial issues |

*CO*, Carbon monoxide; *FeNO*$_{50}$, fractional exhaled nitric oxide at expiratory rate 50 mL/s; *FEV*$_{1}$, forced expiratory volume first second; *ICS*, inhaled corticosteroids; *IgE*, immunoglobulin E; *PI-ED*, pediatric index of emotional distress.

The nurse-led home visit is a pivotal key part of the work-up of problematic, severe asthma[24]; doctors sitting in the clinic know little or nothing of what is really happening at home. Five areas are explored: adherence, tobacco smoke, allergens, psychosocial issues, and asthma education. If the patient has been referred from a distant center, the home visit may be performed by a local specialist nurse after discussion with our own team. This approach may not be feasible everywhere, but in our hands, it allows the identification of significant and potentially reversible factors in more than half of those referred with problematic severe asthma. It is absolutely clear that relying purely on a hospital-based assessment by a pediatrician will lead to many mistakes.

## Adherence

Physician estimates of adherence are notoriously inaccurate, adherence is often poor, and parents overestimate how much medication is being administered. In our hands, questionnaires that rely on self-report, such as medication adherence rating scale (MARS)[66] are not useful.[67] There are multiple reasons for poor adherence.[68,69] The Practicalities and Perceptions Approach (PAPA) helpfully divides these into intentional (e.g., doubts about need for medications, their efficacy, and side effects) and unintentional (e.g., regime impractical because too complex) reasons; clearly different strategies are needed to deal with these. The biggest adherence studies are in children in the community and adult severe asthmatics, rather than severely asthmatic children.[23,70–73] Medication issues are the commonest cause of failure of response to treatment in our severe asthma clinic.

### Prescription Records

We found that less than half the patients had picked up more than 80% of the required prescriptions, and nearly one-third had picked up less than 50% (24), similar to other work.[74] Although those who have not collected prescriptions by definition cannot be using them, electronic monitoring (see later) has shown no relationship in prescription uptake and medication use even in those who do collect prescriptions.[75] We also determine the number of refills forSABA, which have been represcribed; collecting ≥6/year is associated with a poor outcome.[76]

### The Home Visit

Medications were commonly found to be past the expiration date, and 25% could not produce a complete set of in-date medications during the visit. Other issues identified were total inaccessibility of any medications, and medications unopened in their original wrapping, both suggesting nonadherence.[24]

## Parental Supervision

In one study, even young children (20% of 7-year-olds, 50% of 11-year-olds) were left to take asthma medications unsupervised.[77] Often parents think they are supervising treatment, but in fact are actually not directly witnessing the therapy being taken by the child; they are merely calling reminders when the child is upstairs. This situation requires sensitive exploration. When parental supervision is not working, we have used directly observed therapy (DOT) at school, on the basis that 5 days' treatment is better than none. However, this founders if the child does not attend school. Even if the child goes to school, school staff often fail to appreciate that DOT means closely watching the child take the medication with their full attention, not carrying on with other tasks while the child “takes” the medication standing behind their back.

## Use of Inhaler Devices

These are often wrongly used. Regular teaching sessions may lead to improvements,[78,79] but do not guarantee good technique in the long term. However, all the children in our series had had repeated instruction in specialized centers, and yet still had a poor technique. A common adolescent issue is using pressurized metered-dose inhalers without spacers, because spacers are thought to be babyish; however, without a spacer, drug deposition in the lower airway will be minimal.

## Electronic Monitoring: Towards a Definitive Test

We increasingly use electronic monitoring inhalers to assess adherence. We always tell the families that they are being monitored in this way. Our current technology records the time and number of actuations, but not whether the child actually inhaled; this last is a weakness, which means that adherence may still be overestimated. The first lesson we have learned is that all the above methods are inadequate to determine adherence; they can, of course, determine a definitely nonadherent group. Electronic monitoring allows us to divide children who are apparently not responding to treatment into one of three groups requiring different management strategies:

1. The child starts with poorly controlled asthma, often with a reduced $FEV_1$ and $FeNO_{50}$), and is adherent during monitoring. During this time, and despite no change in treatment, asthma control improves, $FEV_1$ rises, and $FeNO_{50}$ falls (Fig. 46.2). This group was clearly previously nonadherent, and when they took the medication they responded well. The treatment is left unchanged, and the findings and ways to maintain adherence are discussed with the child and family.

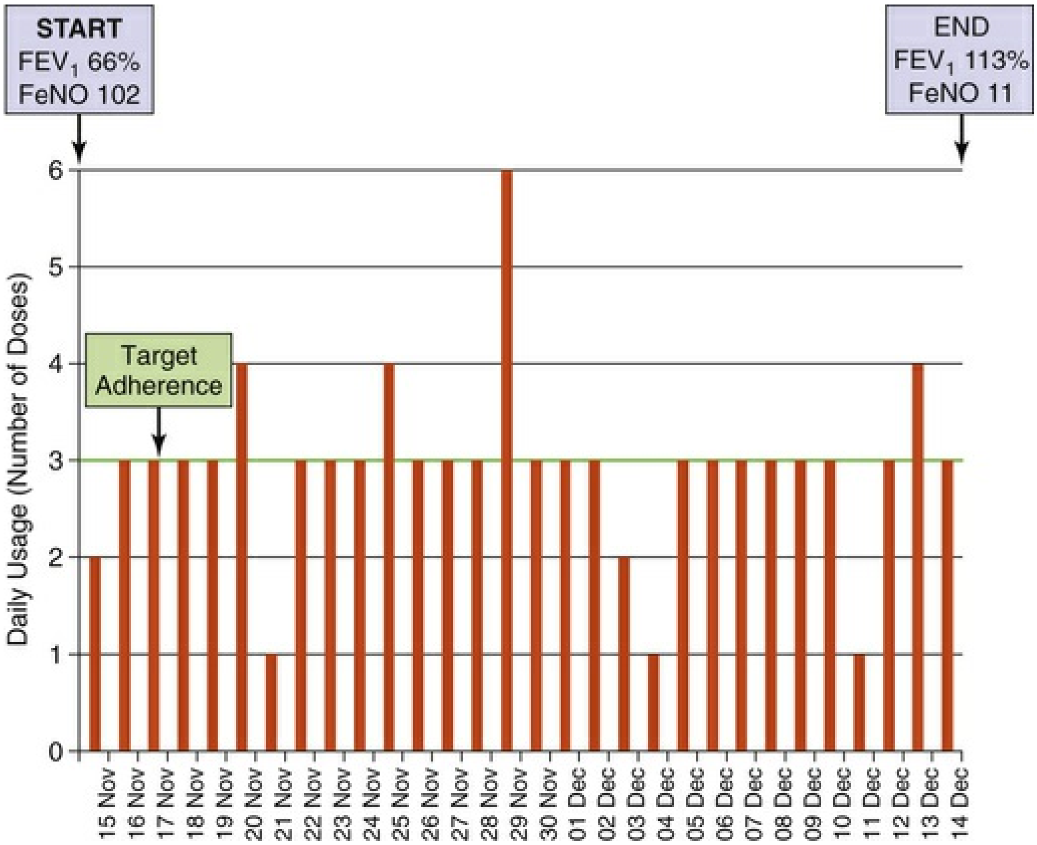


**FIG. 46.2** Electronic monitoring. The adherence is good, and despite no change in treatment, first second forced expired volume *($FEV_1$)* has risen, and fractional exhaled nitric oxide *(FeNO)* has fallen, both becoming normal. The child was clearly nonadherent prior to monitoring. (Courtesy Dr A Jochmann.)

2. The child remains poorly controlled, and does not take the medication during monitoring. There is no point in escalating treatment, and the reasons for nonadherence are explored.
3. The child adheres to treatment well, but the condition remains poorly controlled. The possible explanations include activation of the inhaler without inhalation; environmental factors (below) driving asthmatic inflammation to override the effects of treatment; and true steroid resistance. These different factors are teased out on an individual basis.

On the basis of our experience, we believe that access to electronic monitoring is essential for the proper management of many children presenting with problematic severe asthma.

## Environmental Factors

### Allergen Exposure

Denial of the importance of allergen exposure is common. At a level insufficient to cause acute deterioration, allergen exposure leads to increased airway inflammation, bronchial responsiveness,[80] and steroid resistance via IL-2 and IL-4 dependent mechanisms[81,82] in adults. Allergen exposure in the home, combined with evidence of sensitization, synergizes with viral infection to cause asthma attacks.[83] The relationships between allergen exposure, allergen sensitization, and symptoms, are complex, and may vary from antigen to antigen.[84] Indeed, an allergen may lead to symptoms even without evidence of specific IgE-mediated sensitization.[85,86] Nonetheless, in a child with significant symptoms of asthma, and in particular with severe asthma attacks, it seems reasonable to try to reduce environmental allergen exposure, since neither sensitization nor viral infection can be modulated.

#### Home Exposure.

The aeroallergens likely most susceptible to intervention are pets, cockroaches, molds, and house dust mites (HDM)—with the latter being a controversial area.[87–89] Ideally, we would use environmental dust sampling to determine exposures and any response to avoidance measures. Exposure is common in asthmatics of all severites.[90–92] Pet and cockroach sensitization may be a marker for high morbidity[89,90]; although whether the latter can be separated from the effects of low socioeconomic status is arguable.[93] Passive smoking may increase the likelihood of pet sensitization.[92] The use of synthetic bedding may be associated with severe wheeze.[94] In our study,[24] 17 of 30 children who owned furry pets were sensitized to that pet on SPT, and only two had any allergen avoidance precautions in place. A total of 31 children were clinically thought to have significant HDM exposure; 5 were using comprehensive allergen avoidance measures, 15 partial, and 11 none. Reduction of mold exposure may be particularly important if severe asthma with fungal sensitization (SAFS) is suspected. This is discussed in more detail below.

### School Exposure.

Allergen exposure in school may also be important,[84] but difficult to change. Exposure to cat allergen on the clothes of classmates at school is sufficient to cause deterioration of asthma with a pattern similar to occupational exposure; namely, worsening during the week and improving at weekends, assuming there is no cat in the home.

### Passive and Active Smoking.

Active smoking by adult asthmatics causes steroid resistance,[95–98] and passive smoke exposure likely has the same effect. This is common in asthmatic children,[99–101] being 25% in our series[24]; the prevalence of active smoking as well as other risk-taking behaviors is also likely to be high in children and young people.[102] The mechanisms of tobacco smoke-induced steroid resistance have been researched mainly in adults[103]; the phenotype is neutrophilic. In a pediatric study,[104] we found that parental smoking reduced histone deacetylase protein expression and activity, and reduced the *in vitro* inhibitory effects of dexamethasone on tumor necrosis factor-$\alpha$-induced IL-8 release from alveolar macrophages in severe, therapy-resistant asthma. Bronchoalveolar lavage (BAL) had higher IL-8 concentrations and neutrophil counts and the children had lower

ACT scores compared with nonpassive smoke-exposed children, which are findings supported by adult data. Additionally, it is likely that symptoms are exacerbated by a direct irritant effect of smoke. Other environmental irritants sometimes encountered include incense or joss sticks, and the extensive use of air fresheners and other aerosol sprays. Environmental pollution is also important, but difficult to modulate except at the level of public health.

## Psychosocial Morbidity

The relationships between asthma and the brain are complex. Acute and chronic stress may trigger asthma exacerbations.[105–107] Stress has been shown to amplify the airway eosinophilic response to allergen challenge.[108] Functional magnetic resonance imaging scanning has identified asthma neurophenotypes in circuits that process emotional information, with greater anterior insular activation with asthma-related psychological stimuli, and associated more profound airway inflammatory response and increased disease severity, although which was cause and which was consequence could not be established.[109] We, and others,[24,110] have shown that psychosocial issues are common, especially anxiety and depression. Most issues only emerged during discussions between the nurse and the family in the home. Altogether, about half the families were referred to clinical psychology for a more detailed assessment. It is not productive to try to determine whether anxiety and depression are the cause or result of severe asthma; both are treated on their individual merits.

### Asthma Education

Some adherence issues relate to basic misunderstandings of asthma and the purpose of treatment, and this is also addressed. If the child does not have a detailed asthma plan, this is put in place and communicated to the school. It is hoped that this will have been done previously, but the asthma plan is always reassessed in detail.

### Safeguarding Issues: Symptom Reporting

We have safeguarding concerns in around 10% of children with “severe” asthma. Much relates to symptom overreporting; parents not reporting asthma severity accurately may be the underlying problem, and this is extremely difficult to detect. This is separate from the effect of understandable parental anxiety leading to exaggeration of symptoms. Motivation may include access to financial and other benefits as a result of having a “sick” child, right up to deliberate fabrication of symptoms, or Munchausen by proxy. Unfortunately, diagnosis is often long delayed because a basic tenet of pediatrics is to believe the mother. In such circumstances, contact with the school can be illuminating. Teachers are an important resource; they are experienced in assessing children, and spend many hours each day with them. One child allegedly suffering from severe asthma was, in fact, the captain of sports and was nicknamed “the Greyhound.” The school did not know that the child had a diagnosis of asthma, and had no short-acting β-2 agonist in case of emergency. The lesson here is that early discussion with the safeguarding team is essential if there are any concerns, and that no pediatric referral center for severe asthma can function without access to a really good safeguarding service.

## Increasingly Important in the Assessment Process: A Hospital Admission

We find that an admission to hospital for assessment over 2 weeks is valuable when symptoms are thought to be overreported.[111] A detailed plan is worked out in advance (Box 46.4), including regular measurement of lung function and $FeNO_{50}$; there is a regular program of exercise; all medications are supervised; and no short-acting β-2 agonist is given unless the child has first been assessed. The usual outcome is that the child is well and active without additional rescue medication; their lung function improves; and importantly, the $FeNO_{50}$ falls. This last point cannot be attributed to lack of exercise in hospital. On occasion, the admission serves to rehabilitate the child and demonstrates that exercise is not prevented by asthma; and restored confidence is maintained after discharge. Often, it is clear that the problem is either nonadherence to medication or an adverse home environment, or both, which needs addressing rather than escalating prescribed treatment.

**Box 46.4**

### Sample Admission Plan

The purpose of this admission is to allow a period (usually 2 weeks) of observation and assessment in a controlled and safe environment. As far as possible, normal activities, including attending the hospital school and participating in physical activity, should continue. This is intended as an opportunity to adjust and hopefully reduce some asthma medications.

Admission plan

- To remain resident on the ward during the period of the admission and only leave the ward for short periods with the permission of ward staff or longer trip supervised by a nurse
- Attend school on school days. Our school staff will liaise with the child's school to ensure that appropriate work and, if necessary, assessments are undertaken
- Review by the physiotherapists at the beginning of the admission and a program of physical activity agreed
- Psychology review early on in the admission and further input as decided following the initial consultation
- All medications (including inhalers) are to be kept by the nursing staff and directly observed as per ward policy
- If albuterol is requested, to be assessed by a doctor first and peak flow readings recorded before and after albuterol (and documented in the case notes)
- Morning and evening peak flows every day
- Ward spirometry with bronchodilator reversibility on admission and thereafter on Tuesdays and Fridays
- Exhaled nitric oxide measurements on admission and thereafter on Tuesdays and Fridays
- ACT to be completed at the beginning of the admission

- Paediatric Asthma Quality of Life Assessment to be completed at the beginning and the end of admission
- Regular review by one of the Respiratory Clinical Nurse Specialists. The Difficult Asthma Team will liaise closely with the attending medical team throughout the admission
- Urine cotinine on admission
- Prednisolone level and random cortisol on the day of admission for all children prescribed prednisolone. If not on prednisolone, blood tests including total IgE, specific IgEs, FBC, and other clinically indicated tests can be performed during the first few days of the admission
- Other tests, including histamine challenge, cardiopulmonary exercise test, induced sputum and cardiorespiratory polygraphy, as indicated by the clinical team

*ACT,* Asthma control test; *FBC,* full blood count; *IgE,* immunoglobulin E.

## Difficult Asthma: Summary

This assessment process generates a huge amount of detailed information, and this is reviewed in a dedicated, multidisciplinary team meeting, where we attempt to place the child in one of two categories: (1) difficult asthma, in which comorbidities and environmental/lifestyle factors are responsible for the poor response to treatment; and (2) severe, therapy-resistant asthma, in which atypical airway disease is the cause of the problem. This latter is addressed below. Even though we have shown that many children who are identified as having difficult asthma do well in the medium term with better asthma outcomes and reduction in prescribed medication,[112] it should not be assumed that, just because the child does not need a monoclonal antibody, all will be well. In particular, children from families who continue to exhibit the risk factors identified by National Review of Asthma Deaths (NRAD) (see Box 46.1) are at high risk of severe asthma attacks and death and should be very carefully monitored.

## Severe, Therapy-Resistant Asthma: Deconstructing the Airway Disease

If extrapulmonary and environmental/lifestyle have been excluded, attention switches to the nature of the underlying airway disease. It should be noted that this evaluation cannot separate the consequences of treatment of severe asthma from the nature of the disease itself, for obvious reasons. So the use of high-dose ICS are locally immunosuppressive,[113] and their use in adults has been associated with an increased risk of pneumonia in chronic obstructive pulmonary disease patients,[114] as well as tuberculosis and atypical mycobacterial infection.[115,116] So the finding of bacterial infection or changes in the airway microbiome using molecular techniques cannot be assumed to be causal in severe asthma. There are potentially six components of airway disease (Box 46.5). In most cases of severe asthma, abnormal airway contents (mucus) are a secondary phenomenon, although they are occasionally sufficiently severe as to merit treatment with mucolytics. Likewise, a cough is a secondary phenomenon, and the treatment is of the underlying cause.

**Box 46.5**

### Components of Airway Disease, Their Underlying Cause and Management

| Airway Characteristic | Underlying Cause | Treatable Characteristic |
|---|---|---|
| Fixed airflow obstruction | ▪ Extramural: loss of alveolar tethering<br>▪ Intramural: circumferential narrowing, from antenatal or postnatal exposure to pollutants, postnatal viral infection, or airway remodeling | ▪ Avoid increasing the doses of medications, which will be ineffective |
| Variable airflow obstruction | ▪ Extramural: loss of alveolar tethering<br>▪ Intramural: increased airway smooth muscle, airway edema, any cause of circumferential narrowing<br>▪ Intraluminal: mucus | ▪ SABA, LABA (potentially long-acting muscarinic antagonists) for bronchospasm<br>▪ Airway clearance, mucolytics |
| Airway inflammation | ▪ Present or absent<br>▪ Beneficial (combating infection) or adverse<br>▪ Cell based description: eosinophilic, | ▪ Do not use antiinflammatories if airway not inflamed |

|  |  |  |
|---|---|---|
|  | neutrophilic, mixed cellularity<br>▪ Pathway based description: Type 2 or innate cytokines, other | ▪ Do not suppress if beneficial<br>▪ Specific biologicals will increasingly be deployed in the future |
| Airway infection | ▪ Bacterial, viral, fungal<br>▪ Luminal or latent within airway wall | ▪ Antibiotics and antifungals as appropriate |
| Abnormal airway contents | ▪ Too wet: increased airway surface liquid or mucus; aspiration syndromes<br>▪ Too dry: increased airway surface liquid absorption | ▪ Airway clearance, treat any reflux, assess swallowing<br>▪ Rehydrate with hypertonic saline aerosols |
| Abnormal cough reflex | ▪ Increased cough sensitivity<br>▪ Reduced sensitivity | ▪ No licensed pediatric therapies as yet |

*LABA*, Long-acting beta-2 agonists; *SABA*, short-acting beta-2 agonists.

There are a number of differences between the typical severe, therapy-resistant asthmatic child and the picture in adults. In our series, there was no female predominance; a strong atopic history was common (85% atopic with a total median IgE of 386 [range: 115-1286]).[117,118] Also, the children were not obese. U-BIOPRED is a large Pan-European study recruiting adults and children with severe asthma and comparing them to mid-moderate controls. Although the adult severe asthmatics had significantly worse lung function and higher FeNO than the controls, these were not significantly different in the pediatric cohorts. In both adults and children, asthma-related quality of life was significantly worse in the severe groups.[51,119]

The main focus of the evaluation is on fixed and variable airflow obstruction, and airway inflammation and infection; four key questions are answered (Box 46.6).

### Box 46.6

## The Four Key Questions Answered by Invasive Investigation of Children With Severe, Therapy-Resistant Asthma

1. Is there phenotype discordance, namely a disconnect between symptoms and eosinophilic airway inflammation?

Antiinflammatory medication is not escalated if the airway is not inflamed, and should be intensified in an exacerbating child if there is airway inflammation when the child is asymptomatic.

2. Is the airway inflamed at all, and if so, what is the pattern of inflammation? (Usually neutrophilic) inflammation may be a beneficial response to infection.
3. Is the child partially or totally steroid responsive, or steroid resistant, according to our multidimensional framework?
4. Does the child have persistent airflow limitation? Therapy for airflow obstruction is not escalated if the child has reached the plateau of the dose-response curve in terms of spirometry.

## Protocol: Invasive Investigation of Severe, Therapy-Resistant Asthma

We assess symptoms (ACT), recent steroid bursts, spirometry, and acute response to bronchodilator, sputum induction, and $FeNO_{50}$. The same day, the child undergoes a bronchoscopy under a general anesthetic, with BAL and endobronchial biopsy.[118,120] When the samples have been obtained, and at the end of the procedure, we administer a single dose of intramuscular triamcinolone (40 mg if the child's weight <40 kg, otherwise 80 mg). The child is discharged the next day and is reviewed 4 weeks later, when all the noninvasive measurements are repeated (Fig. 46.3).

INDIVIDUALIZED TREATMENT PLAN

**FIG. 46.3** Invasive investigation of putative severe, therapy-resistant asthma. *BAL,* Bronchoalveolar lavage; *BDR,* bronchodilator responsiveness; *EBx,* endobronchial biopsy; *FeNO$_{50}$,* fractional exhaled nitric oxide at expiratory rate 50 mL/s; *IM,* intramuscular.

The key requirement for the safe performance of bronchoscopy in these children is a skilled anesthesiologist. The child may be premedicated with SABAs, and adverse events are very rare. We saw an acute severe bronchospasm on one occasion, which rapidly responded to treatment. Close postprocedure monitoring of the child is essential.

## Assessment of Airway Inflammation

We do not see submucosal neutrophilic inflammation in children with severe asthma,[118] unlike in adult severe asthma. Interestingly, intraepithelial neutrophils are associated with *better* markers of asthma control, which underscores that possibly some forms of inflammation may be beneficial.[121] Instead, induced sputum, BAL, and the bronchial submucosa are eosinophil dominated, although there are marked variations between individuals in the extent of eosinophilia, including their complete absence. A neutrophilic submucosa should prompt reconsideration of the diagnosis of asthma. Although the findings in induced sputum and BAL are concordant, airway wall histology is discordant.[122] It is not clear which is most relevant to disease pathophysiology.

However, as an increasing array of monoclonal antibodies are coming on the market, we need to move from cell-based descriptions to pathway based, if these expensive resources are to be targeted properly. Given the marked eosinophilic phenotype, a $T_H2$ cytokine profile would be expected, and is indeed found in adult asthma, but two pediatric severe asthma studies have failed to confirm this. We studied both induced sputum and BAL using both the Luminex and the Cytometric Bead Array platforms, and performed immunohistochemistry on endobronchial biopsies. We found scant evidence of the $T_H2$ signature cytokines IL-4, IL-5, and IL-13.[118] The Severe Asthma Research Program group also failed to find evidence of $T_H2$-driven inflammation.[123] They compared severe, therapy-resistant asthma with mild-moderate disease and showed that the cytokines that best discriminated between the two groups were GRO (CXCL1), RANTES (CCL5), IL-12, IFN-$\gamma$ and IL-10. They concluded that pediatric severe, therapy-resistant asthma was neither a $T_H1$- nor a $T_H2$-driven disease. We do not know if some eosinophilic children are $T_H2$ high, and the noneosinophilic group corresponds to $T_H2$ low adult disease.[124] It should be noted that periostin, a useful serum biomarker in adults for the $T_H2$ high phenotype, is not useful in children because it is released from growing bone. The other two discriminatory genes, CLCA1, and SERPINB2, have not been evaluated in children.

The findings of these two large studies do not necessarily show that $T_H2$ cytokines are unimportant in the early stages of severe asthma. All these children were prescribed high-dose ICS, which may have controlled the $T_H2$ component of their disease. What it does mean is that the factors driving ongoing severe disease are different, and are, as yet, unknown. There is increasing evidence that the epithelial-derived cytokines (IL-25, IL-33, and TSLP) may be implicated, as well as lineage-negative innate lymphoid cells.[125] We have shown that IL-33 is steroid resistant and promotes collagen synthesis from fibroblasts from pediatric severe asthma patients.[126] We also showed that increased cellular expression of IL-33, but not IL-13, was associated with increased reticular basement membrane thickness in endobronchial biopsies. IL-33 also stained strongly in the endobronchial biopsies, and the results were supported by animal data. In adults, the monoclonal antibody AMG 157, which prevents TSLP interacting with its receptor, led to marked attenuation of both the early and the late phase allergen responses in adults with mild asthma,[127] which was a surprising finding given that only a single cytokine was blocked.[128] In contrast, the innate epithelial cytokine IL-25 may be more important in mild asthma. Compared with controls, corticosteroid-naïve asthmatic adults stained positive for IL-25 in the bronchial mucosa; in neither group was TSLP or IL-33 detected. IL-25 high patients were identified by bronchial brushing IL-25 transcript levels, and these were reflected in plasma IL-25 levels. A raised plasma IL-25 correlated with increased sputum and endobronchial biopsy eosinophils and a better response to ICS.[129]

The $T_H17$ pathway has been studied in adults, but it would probably drive a neutrophilic phenotype, and thus is an unlikely candidate in children. However, in animals at least, IL-17 is also an eosinophil chemoattractant.[130,131] A recent adult trial of the monoclonal anti-IL-17 receptor antibody brodalumab was negative,[132] perhaps because neutrophilic asthma was not an entry criterion. Further work is clearly needed in order to delineate the proinflammatory mechanisms driving pediatric severe, therapy-resistant asthma.

There is certainly a pressing need to define these pathways. Studies of anti-$T_H2$ cytokine strategies, such as mepolizumab (anti-IL-5),[133] lebrikizumab (anti-IL-13),[134] and dopilumab (IL-4 receptor alpha chain)[135] have often recruited children aged 12 and over, and trials are largely dominated by adult participants. It is essential that promising results in these trials are not uncritically extrapolated to children. It may be justified to perform a therapeutic n of 1 trial in a child doing badly on all therapies. Further trials in children are needed, including measurements of $T_H2$ cytokines, before wide usage in pediatric severe, therapy-resistant asthma can be recommended.

## Assessment of Steroid Responsiveness

It is likely that steroid responsiveness is a continuum; true steroid unresponsiveness is likely confined to rare cases of mutations in the corticosteroid receptor. The widely accepted adult definition of steroid response[136,137] is ≥15% predicted increase in $FEV_1$ in patients with a bronchodilator reversibility (BDR) ≥12% from baseline and an abnormal $FEV_1$ (≤80%) prior to the trial. There is no accepted definition in children, and the adult definition cannot be applied to around half of our severe, therapy-resistant asthmatics, mainly because their baseline spirometry is not sufficiently abnormal prior to the trial[118]; and indeed, spirometry is often a poor reflection of asthma severity in children (above). Furthermore, there is no consensus on the dose and duration of CS for the trial. We opted to use triamcinolone intramuscularly to ensure adherence. We use a multimodality definition of steroid responsiveness (Table 46.3).[6,138] Most children are partial responders; about 10% are total nonresponders, and 10% completely responsive in all domains (complete responders). Some children who were nonresponsive using the adult definition were partial responders in the multidomain assessment. We have also shown that additional doses of triamcinolone do not change the category of responsiveness (unpublished). While the clinical utility of this approach has yet to be confirmed, it might serve as a useful template for current research; so, for example, an intervention with an antiinflammatory medication might be expected primarily to affect the inflammatory domain. Indeed, we have shown that steroid response in the inflammatory domain is predictive of a therapeutic response to omalizumab.[139]

## Table 46.3

**Multidomain Definition of Steroid Responsiveness**

| Domain | Response Pattern 4 Weeks After Intramuscular Triamcinolone |
|---|---|
| Spirometry ($FEV_1$) | Increase in $FEV_1$ (% predicted) to normal (≥80%) or by ≥15% over baseline |
| Symptoms (ACT) | Increase to normal or by ≥50% or by ≥5 points |
| FeNO | Normalizes (<24 ppb) |
| Sputum eosinophils | Normalizes (<2.5%) |

Response may be complete (all domains), partial (≥1 domain) or absent (no domains), of which partial is much the commonest.

*ACT,* Asthma control test; *FeNO,* fractional exhaled nitric oxide; *$FEV_1$*, first second forced expired volume.

# Assessment of Persistent Airflow Limitation

The definition of persistent airflow limitation (PAL) is relatively easy, $FEV_1$ <80% (or better, −1.96 Z [standard deviation] scores) despite a trial of systemic steroids and acute administration of SABA. However, as above, the dose, duration, and route of administration of steroids are still not agreed on, nor is the dose of SABA. We have shown that neither 40 mg prednisolone for 2 weeks[140] nor a single dose of triamcinolone combined with 1 mg albuterol inhaled from a large volume spacer[141] is adequate to determine whether the child has PAL, but it is doubtful whether a higher or longer duration of systemic steroids can be justified. So we have taken the pragmatic decision that PAL will be at least provisionally diagnosed after a single dose of triamcinolone and albuterol, as above. Using this definition, approximately 25% of our severe cohort have PAL.

# Treatment of Severe, Therapy-Resistant Asthma

The treatment options, with the exception of the use of omalizumab, are largely anecdote based.[142] The following scheme is suggested.

1. *Is omalizumab indicated?* Much of the omalizumab evidence is inevitably in less severe asthma,[143–153] but if the child meets national guidelines for asthma, AND has been assessed in detail as above, AND been found to have persistent eosinophilic airway inflammation on bronchoscopy, AND every effort has been made to reduce the allergen burden in

the environment, then we recommend a 16-week trial of omalizumab, with detailed monitoring of the response. Although guidelines mandate aeroallergen sensitization, omalizumab may be trialed in the rare nonatopic child with IgE in the range where omalizumab is indicated.[148] If, after 16 weeks, there is no benefit, we discontinue therapy. Steroid-responsive inflammation may predict a good response to omalizumab (above).[139]

2. *Should standard medications be used in novel ways?* The options are high-dose ICS, fine-particle ICS, oral prednisolone, intramuscular triamcinolone, and the SMART regime. The latter is a single combination ICS and LABA device (usually a Symbicort turbohaler); and low-dose theophylline (antiinflammatory dose). For all but the SMART regime, the demonstration of ongoing eosinophilic airway inflammation is essential (the exception is theophylline, which may benefit neutrophilic asthma, at least in adults[154]); and steroid total nonresponders who have eosinophilic or neutrophilic inflammation should only be considered for low-dose theophylline, and not the steroid-based regimes.
    - *High-dose ICS:* for most children, the plateau of the ICS dose-response curve is 100 μg twice daily of fluticasone,[10] and escalation of dosing risks increased side effects. However, a small minority of asthmatic children may benefit from increasing the dose as high as 2000 μg/day.[155] However, if there is no response to dose escalation, it is essential that it is promptly stepped down to the lowest possible dose.
    - *Fine-particle ICS:* there is evidence from adult studies that some asthmatics may have very distal inflammation, shown on transbronchial biopsy (TBB).[156–158] These studies have not been performed in children because of fears of the risks of TBB. There is also physiological evidence from $C_{alv}$ nitric oxide measurements of distal airway inflammation in adult asthmatics, with responses both symptomatically and physiologically to fine-

particle ICS or systemic steroids.[159,160] There is too much variability in $C_{alv}$ for it to be used as a biomarker in individual children[161]; and there is no evidence for this approach in severe, therapy-resistant asthma. However, a trial of fine-particle ICS may be worth considering, and discontinuing if there is no benefit. Finally, it is interesting to speculate whether the distal airway inflammation is related to the poor peripheral deposition of ICS, and might respond to low-dose oral prednisolone, delivering the steroid by the blood rather than the airway.

- *Oral prednisolone:* the nonevidence-based starting dose is 0.5 mg/kg, tapering down to the lowest dose needed to control the disease. If this is at the price of unacceptable side effects, then a steroid-sparing agent (see later) should be considered.
- *Intramuscular triamcinolone:* there is no evidence that this offers any advantage other than assuring adherence, which is an insufficient reason for using it other than for a steroid trial (see earlier). Indeed, if it is used as a “quick fix” for nonadherence, there is a risk that this will lead to long-term use with severe steroid side effects.
- *SMART regime*[162–164]: we use this approach particularly in adolescents, to try to keep the regime simple. We also consider its use in the child with symptoms and ongoing peak flow variability, but without evidence of eosinophilic airway inflammation. It could be argued that a LABA, as a single inhaler added to the child's base medications, would be more logical, but given the risks of LABA as a single agent, we prefer the compromise of the additional ICS. The risk of this strategy is that it relies on adequate symptom perception, which may not always be the case in children with severe asthma (see earlier).

- *Low-dose theophylline:* there is laboratory evidence and data from adult studies, that theophylline in a dose attempting serum levels of 5–10 μg/mL may have significant antiinflammatory effects, and restore steroid responsiveness—the latter making it attractive particularly in steroid complete nonresponders.[165–172] The lower serum levels reduce but do not eliminate the risk of drug interactions and other side effects. Despite the strong theoretical background, this approach has rarely been successful in our hands.

3. *Does the child meet criteria for SAFS?* The fungi that are implicated in this condition are listed in Box 46.7 and the definition of SAFS[173] is given in Table 46.4. The results of trials of antifungal therapy in adults conflict with itraconazole[173] but not voriconazole,[174] showing benefit. Fungal sensitization in children may be associated with a more severe phenotype,[175] but there are no randomized, controlled trials of treatment. Our approach is to minimize environmental fungal exposure in the home, including checking any nebulizer the child may have for fungal contamination, and banning visits to stables (by analogy with management of allergic bronchopulmonary aspergillosis [ABPA] in cystic fibrosis). If antifungals are to be used, it is essential to remember that there is an interaction with ICS, such that iatrogenic Cushing syndrome may be seen.[176–179] Anecdotally, antifungals have been successful in some children. Recent evidence suggests that the innate epithelial cytokine IL-33 may be implicated in the pathogenesis of SAFS[180]; however, as yet, there is no clinically approved monoclonal that can be used.

The fungal asthma sensitization trial (FAST) study. *Am J Respir Crit Care Med.* 2009;179:11-18 and Castanhinha S, Sherburn R, Walker S, et al. Pediatric severe asthma with fungal sensitization is mediated by steroid-resistant IL-33. *J Allergy Clin Immunol.* 2015;136:312-322.

4. *Should nonstandard medications be used?* The possible approaches are macrolide antibiotics, immunosuppressives, intravenous Ig as an immunomodulator, and a continuous subcutaneous infusion of terbutaline.
    - Macrolide antibiotics are the safest option, and might be indicated for the rare child with a neutrophilic phenotype, or if an atypical infection is suspected.[181,182] One study comparing azithromycin with montelukast as add-on therapy ended in futility,[183] as only 55 of 292 of those who were symptomatic while prescribed ICS and LABA could be randomized; most of the rest were nonadherent or did not have asthma at all, which

underscores the need for detailed evaluation of these patients before uncritical acceptance of the diagnosis "severe asthma." However, in the small group actually studied, the results were not encouraging. In an adult study, azithromycin reduced asthma attacks only in noneosinophilic patients. Data in children with severe asthma but no airway eosinophilia are awaited.

- *Ig infusions:* the evidence is scanty in adults, and it is anecdotal and conflicting in children.[184–187] As with immunosuppressives (see later) they are used only in children with evidence of ongoing airway inflammation, which is either steroid resistant or only responsive at the cost of major side effects. One small study in steroid-dependent teenage asthmatics showed a reduction in maintenance oral steroids, steroid bursts, and hospitalizations for asthma. They suggested that the mechanism may be a synergistic interaction with dexamethasone in suppressing lymphocyte activation and significant improvement in the glucocorticoid receptor binding affinity.[188] In view of how tightly Ig use is controlled, it would be difficult to justify this approach to regulatory bodies.
- Immunosuppressives are used in children on the basis of small case series (methotrexate,[189,190] cyclosporine[191]) or zero published evidence (azathioprine). Nebulized cyclosporine might be an attractive way of getting benefits while avoiding systemic toxicity, but it has only been used after lung transplantation.
- Subcutaneous terbutaline infusions may be considered in children with ongoing documented labile airflow obstruction and no underlying airway inflammation.[192] This is a rare group, and the evidence base is a small case series. We now perform a double blind n of 1 therapeutic trial,

but rarely find any benefit.

5. *What about other biological agents?* The differences in pathophysiology between childhood and adult severe asthma have been highlighted above. Nonetheless, in a child who has persistent eosinophilic inflammation with ongoing symptoms, either totally steroid responsive or suffering major steroid side effects—in particular in the rare child in whom $T_H2$ activation can be documented—a trial of one of the monoclonal $T_H2$ strategies (above) could justifiably be sought on compassionate grounds.
6. *Physical methods?* There is no evidence to recommend bronchial thermoplasty in children; indeed, the potential long-term consequences of the procedure on the growing airway are worrying.

## A Difficult Specific Problem: Treatment of the Exacerbating Phenotype

Acute asthma exacerbations cause considerable morbidity, sometimes death; however, they are not a feature of all children with asthma. Asthma lung attacks (a term we favor over "exacerbations") have been associated with an accelerated decline in lung function in children not prescribed ICS. Acute asthma lung attacks cannot be abolished completely. Acute asthma lung attacks and loss of baseline control are not the same thing; loss of baseline control is characterized by wide diurnal peak expiratory flow variation, while acute asthma lung attacks are characterized by a steep decline in peak flow, with no increased variability.[193] Children may have good control, but still have attacks,[194] and increasing the interval medications merely increases the risk of side effects. However, poor control[195] and previous severe attacks[195,196] both predict a high risk of future acute attacks.

In older children, the combination of respiratory viral infection, and both sensitization and exposure in the home to high allergen levels, is strongly predictive of asthma lung attacks.[83] They are typically characterized by mixed eosinophilic and neutrophilic, or pure neutrophilic inflammation.[197–199] At the other extreme, really high-dose allergen exposure can cause acute asthma lung attacks (e.g., thunderstorm asthma,[200] and the Barcelona soya bean epidemic asthma[201]); thunderstorm asthma at least is characterized by airway eosinophilia.[200]

In school-aged children with multiple asthma lung attacks, we aim to increase the baseline dose of ICS to abolish interval sputum eosinophilia, the effects of which are best shown through the proof of concept anti-IL5 studies.[202,203] LABAs also reduce asthma lung attacks.[204–206] Allergen sensitization is identified, and avoidance measures advised. High-dose ICS[207] or LTRAs[208] may be considered at the first sign of a viral asthma lung attack. However, none of these measures will completely obviate the need for oral CS. Finally, if asthma lung attacks are of very sudden onset with rapid deterioration over minutes, we provide the child with a source of injectable adrenaline (Epipen). The hospital treatment of acute asthma lung attacks is beyond the scope of this chapter.

# Monitoring the Child With Severe, Therapy-Resistant Asthma on Treatment

## Monitoring Treatment Benefit

On the basis of work in adult asthmatics, it may be thought that monitoring therapy in the inflammatory phenotypes would be beneficial in children,[209,210] but the only trial in children with severe, therapy-resistant asthma using induced sputum every 3 months was negative.[211] A *post-hoc* analysis did suggest a reduction in acute asthma attacks in the month after the sputum measurement; however, currently, there is insufficient evidence to recommend induced sputum or $FeNO_{50}$ to monitor severe asthma. Two studies may help explain the reasons. In the first, the variability of sputum phenotype longitudinally was determined in children with either mild/moderate or severe asthma, and spontaneous phenotype changes were common in both groups, and not predictable. This is in marked contradistinction to adult results in which they appeared much more stable over time.[212] A second study reported the relationship between sputum eosinophil count and $FeNO_{50}$ in severe therapy-resistant asthma. A total of 148 samples were concordant (eosinophil positive, $FeNO_{50}$ positive = 77; both negative = 71) and 49 (25%) were discordant (eosinophil positive, $FeNO_{50}$ negative = 25; eosinophil negative, $FeNO_{50}$ positive = 24). Fifty-nine children produced at least two sputum samples. Of these, 31 (53%) were consistently concordant, 24 (41%) were discordant in one sample but concordant on at least one other occasion (one showed discordance in both directions and concordance in a third sample), and only 4 (7%) demonstrated consistently discordant levels.[213] Thus, these two markers cannot be used interchangeably, and neither can currently be recommended for monitoring children with acute severe asthma.[214]

## Monitoring Side Effects

In addition to standard monitoring for both asthma and systemic steroid therapy, the question of adrenal insufficiency must be considered. Clearly, adrenal suppression is inevitable if the child is on all but the lowest dose of oral steroids. Most would recommend a Synacthen test for children on high-dose ICS, but the dose of adrenal corticotrophin, the sampling protocol, and the frequency that the test is performed are still controversial. Our current recommendation is for an annual standard Synacthen test.

## The Role of an Annual Assessment

There is a strong case to be made for a structured annual assessment in all children with severe, therapy-resistant asthma. This would include a reevaluation of adherence (see earlier) and allergen exposure, as well as at least screening questionnaires for psychological morbidity. Spirometry and acute bronchodilator responsiveness, sputum induction, and at least $FeNO_{50}$ should be part of the evaluation too. This would also be the opportunity to evaluate side effects with measurements of height and weight, blood pressure, urinalysis, and the performance of a short Synacthen test. We do not routinely refer for ophthalmology examination. Following this reassessment, a multidisciplinary planning meeting is held. An annual review should not replace a much more frequent and regular review of treatment and progress.

## Summary and Conclusions

Severe asthma continues to be one of the most challenging problems in the whole of pediatrics. The need to get the basics right is and will remain the bedrock of management. Children are not small adults, and pediatric asthma is not a watered-down version of adult asthma. With the advent of the new era of monoclonals, we need pediatric biomarkers and clinical trials to define who will benefit from which monoclonal. Recent lessons learned the hard way are:

- Unless you are doing electronic adherence monitoring, you are clueless about whether the patient is adherent to therapy; this has become pivotal in severe asthma clinics.
- It is also increasingly clear that child abuse will present as severe asthma, and many so-called severe asthmatics are in fact no such thing; this is an instance where believing the mother may not always be the right approach. Always talk to the school; always get the details of what objective evidence there is for “severe” asthma attacks; and, if in doubt, admit the child for observation and objective monitoring.

Without doubt, there will be more painful lessons to learn in the coming years.

## 47

# The Influence of Upper Airway Disease on the Lower Airway

*Jonathan Corren MD*

During the past century, practicing clinicians have frequently observed that allergic rhinitis, sinusitis, and asthma coexist in the same patients. Despite a wealth of data supporting an association between the upper and lower airways, not until recently have reliable data emerged that suggest that upper airway disease is a risk factor for the development of asthma and that experimentally induced nasal dysfunction causes asthma to worsen. In addition, there is a growing body of literature demonstrating that appropriate treatment of nasal allergy and chronic sinus disease results in improvements in asthma symptoms and lower airway function. In this chapter, data from a variety of epidemiologic, clinical, and laboratory studies will be highlighted to help clarify our understanding of these complex and important relationships.

## Allergic Rhinitis and Asthma

## The Epidemiologic Relationship Between Allergic Rhinitis and Asthma

The first population-based studies that explored the relationship between allergic rhinitis and asthma were cross-sectional surveys, which demonstrated that rhinitis and asthma commonly occur together. Many of these studies reported that nasal symptoms occur in 28%–78% of patients with asthma[1] as compared with approximately 5%–20% of the general population.[2] Generally, these data were drawn from a variety of epidemiologic studies and clinical settings in which patients were not interviewed in a standardized fashion and insensitive instruments were used for detecting rhinitis. In a study that utilized a standardized and detailed questionnaire in 478 patients across all age groups, rhinitis was found to be a nearly universal phenomenon in patients with allergic asthma, occurring in 99% of adults and 93% of adolescents.[3] Conversely, asthma has been shown to affect up to 38% of patients with allergic rhinitis,[1] which is substantially higher than the 11.9% global prevalence noted in unselected children.[4]

While these studies demonstrate that rhinitis and asthma frequently occur in the same patients, longitudinal studies are required to accurately assess the actual risk for developing asthma in patients with rhinitis alone.

Settipane and colleagues[5] published the first prospective study regarding the relationship between allergic rhinitis and the development of asthma. In a study that spanned 23 years from entry to completion, 690 adolescents who had allergic rhinitis (without chest symptoms) developed asthma 3 times more often (10.5%) than individuals without rhinitis (3.6%). In another prospective study, Burgess and coworkers[6] enrolled 8583 children, beginning at 7 years of age, and evaluated them at 13 and 43 years of age. Children diagnosed with allergic rhinitis at the beginning of the study had a twofold to sevenfold increased risk of developing asthma at both 13 and 43 years of age. In the most recent study, Rochat and colleagues[7] followed 1314 healthy children from birth to 13 years of age. Allergic rhinitis present at 5 years of age was found to be a significant predictor for developing wheezing between 5 and 13 years of age, with an adjusted relative risk of 3.82. These longitudinal studies, taken together, strongly support the role of allergic rhinitis in childhood or adolescence as a risk factor for developing subsequent asthma.

In children younger than 2 years of age, it has been more difficult to prospectively assess the progression of allergic rhinitis to asthma, in part due to the high prevalence of viral upper respiratory tract infections in this age group. In the study by Rochat,[7] children with allergic rhinitis diagnosed by 2 years of age were not at increased risk of developing wheezing between 5 and 13 years of age. The authors noted that rhinitis at 2 years of age is usually not a persistent condition and will often remit as the child grows older.

Studies dating back over 20 years have demonstrated that adults and adolescents with allergic rhinitis are more likely to have increased bronchial hyperresponsiveness (BHR) than children without rhinitis.[8] More recently, airway hyperresponsiveness has also been shown to be increased in children who have allergic rhinitis but no asthma. Choi and colleagues.[9] performed bronchial methacholine challenges in a group of 115 nonasthmatic children, 4–6 years of age. BHR, assessed as a methacholine dose required to produce wheezing or oxygen desaturation of <8 mg/mL, was significantly more common in children with allergic rhinitis compared with nonrhinitis children (32.5% vs. 9.4%, respectively). Among children with allergic rhinitis, serum total IgE, the number and pattern of skin-prick test responses, blood eosinophil markers, and parental history of allergic rhinitis and atopic dermatitis were not different between the BHR-positive and BHR-negative groups, whereas the persistent type of rhinitis and parental history of asthma were more frequent in the BHR-positive group than in the BHR-negative group.

While nonspecific BHR appears to be more common in children with allergic rhinitis, a second and equally important question is whether this characteristic predisposes them to the development of asthma. A 12-year follow-up study of 291 randomly selected children and adolescents (7–17 years of age) examined a number of historical and laboratory features, including bronchial responsiveness to inhaled histamine.[10] Increased airway responsiveness to histamine was a powerful independent predictor of future lower airway disease, with an approximate fourfold increased risk of developing symptomatic asthma during this period of observation. In a second study, Ferdousi and colleagues[11] followed up a much smaller group of children ($n = 28$) for only 2 years. Sixteen of the 28 children were found to have an increase in BHR (assessed by isocapnic hyperventilation of cold air or inhaled methacholine challenge), and 8 of these 16 developed asthma after 2 years.

These studies support the theory that bronchial hyperreactivity may represent an intermediate phase between nasal allergy and symptomatic asthma and may help identify children and adolescents at highest risk for developing asthma.

Pharmaco-economic studies from the past decade have attempted to correlate the presence of rhinitis with asthma severity and health care costs attributable to asthma. In an analysis of a database of 1261 children with asthma, Huse and colleagues[12] compared patients with significant nasal allergy with those who had mild or no symptoms of nasal disease. These investigators noted that patients with more severe rhinitis were much more likely to have nocturnal awakening caused by asthma (19.6% vs. 11.8%, respectively), “moderate to severe asthma” as defined by the National Asthma Education Program (60.2% vs. 51.2%, respectively), or work loss related to asthma (24.1% vs. 21.1%, respectively). Similarly, Halpern and coworkers[13] observed that patients with symptomatic rhinitis used more asthma medications, particularly more inhaled and supplemental oral corticosteroids. Judging from these recent investigations, one can postulate that allergic rhinitis may also be related to increased asthma severity and the use of more potent antiasthma medications. Although these data suggest that rhinitis may be contributing to asthma, an alternative explanation for this association may be that nasal inflammation is a marker for increasing dysfunction of the entire respiratory tract. The possibility of a cause-and-effect relationship is better addressed by therapeutic studies of rhinitis therapy in patients with asthma.

It has been speculated that allergic rhinitis may add a significant burden of disease to patients with asthma. A survey of approximately 800 parents of children with asthma attempted to determine the impact of nasal disease upon their quality of life.[14] In three-quarters of children, rhinitis symptoms preceded the diagnosis of asthma. The concomitant presence of nasal allergy and asthma disrupted the ability to get a good night's sleep (79%), to participate in leisure and sports activities (75%), to concentrate at work or school (73%), and to enjoy social activities (51%). Importantly, parents (79%) reported worsening asthma symptoms when nasal symptoms were most active, and many (56%) avoided the outdoors during the allergy season because of worsening asthma symptoms. The majority of the parents (60%) indicated difficulty in effectively treating both conditions, and 72% were concerned about using excessive medication. Information collected from this study and other similar data indicate that allergic rhinitis does impose a significant additional symptomatic burden on patients with asthma.

## Common Immunopathology of Allergic Rhinitis and Asthma

During the past decade, we have learned that the immunologic processes leading to allergic rhinitis and atopic asthma are the same. A large number of studies have examined the composition of inflammatory cell infiltrates in the nasal and bronchial mucosa of patients with allergic rhinitis and asthma. Critical cells that have been consistently identified in both upper and lower airway tissue include both resident (epithelial cells, mast cells, dendritic cells) and infiltrating cell types (eosinophils, Th 2 cells).[15,16]

Allergen provocation studies have also demonstrated striking similarities between immunopathologic processes in the nasal and bronchial mucosa, including allergen-induced infiltration by inflammatory cells, cellular activation, and cytokine and chemokine expression or production.[17] In addition, the development of early- and late-phase reactions and the acquisition of airway hyperresponsiveness have been convincingly demonstrated in both the nasal and the lower airways after allergen provocation.[18]

Histologic studies of individuals with allergic rhinitis and no evidence of clinical asthma consistently demonstrate abnormalities of the bronchial mucosa, including thickening of the lamina reticularis and mucosa eosinophilia. These abnormalities are generally less pronounced than those of asthmatic patients,[19] but sometimes, the findings in subjects with rhinitis are indistinguishable from those in subjects with mild asthma.[20] A recent investigation of this phenomenon confirmed that airway inflammation in allergic rhinitis is midway between normal controls and asthmatics and that asthmatics have much lower levels of interferon gamma than these other two groups, indicating that this cytokine may be an important regulator of the asthma phenotype.[21] Findings from these and other histologic studies demonstrate that both the upper and lower airways are histologically and functionally abnormal in patients with rhinitis and no asthma and that select cytokines may determine which patients manifest clinical signs and symptoms of asthma.

## Effects of Rhinitis Therapy on Asthma

Physicians often note anecdotally that treatment of allergic nasal disease results in improvements in asthma symptoms and pulmonary function. However, there have been relatively few well-controlled, large-scale clinical trials that have attempted to quantify this effect.

### Intranasal Corticosteroids

Intranasal corticosteroids (INS) are widely recognized as the most effective pharmacotherapy for allergic rhinitis, with potent effects on symptoms, nasal physiology, and upper airway mucosal inflammation. Given the important pairing of nasal disease and asthma, it therefore stands to reason that treatment of rhinitis with INS might have a salutary effect on the lower airways. During the past 25 years, a large number of clinical trials have been conducted to determine the effects of INS on asthma outcomes. A recent systematic review and meta-analysis examined all prior studies of INS in patients with allergic rhinitis and concomitant asthma and identified a total of 18 randomized, controlled studies with 2162 patients for inclusion in the analysis.[21a] Asthma outcomes consisted of pulmonary function (including first second forced expired value ($FEV_1$) and domiciliary peak expiratory flow rate), measures of nonspecific bronchial responsiveness, asthma symptoms scores, asthma-specific quality of life, and rescue bronchodilator use. Statistical analysis of a subgroup of studies that compared INS with placebo demonstrated significant improvements in all the above parameters, including $FEV_1$ (standardized mean difference [SMD] = 0.31, 95% CI, 0.04–0.08) and asthma symptoms (SMD = −0.42, 95% CI, −0.53 to −0.30). Importantly, there were no significant changes in asthma outcomes when INS were added to orally inhaled corticosteroids, suggesting that the impact of INS on chronic lower airways symptoms may be strongest in patients who are not receiving adequate asthma therapy. While these data are helpful in assessing the effects of INS on daily asthma outcomes, such as lung function and symptoms, the studies included in the meta-analysis were not designed to examine the effects of nasal therapy upon asthma exacerbations.

In addition to the above-randomized studies, clinical data from large populations has been employed to assess the relationship between INS use and asthma exacerbations and asthma-related resource utilization.[22,23] A nested case-control study was performed using claims records from 215,000 members, age 6 years and older, of a managed care organization in the United States.[22] Patients with both allergic rhinitis and asthma were identified and assessed for types and numbers of prescriptions for these conditions along with hospital-based care (emergency room visits and hospitalizations) for asthma. Patients who had used INS had a significantly lower risk for both asthma-related emergency room treatment and hospitalization (adjusted odds ratios: ER, 0.75, 95% CI, 0.62–0.91; hospitalization, 0.56. 95% CI, 0.42–0.76). These data suggest that use of INS may have an effect on major exacerbations of asthma, although it is uncertain whether this is a direct effect of rhinitis therapy or may reflect better overall care of the asthmatic patient.

Both the randomized trials and large database analyses indicate the potential importance of INS in reducing both daily assessments of asthma control (symptoms, beta-agonist use, and pulmonary function in patients not receiving inhaled corticosteroids [ICS]) and asthma exacerbations. As most of the INS preparations that were used during the above studies have very limited systemic availability, it is unlikely that these effects were due to systemic effects of the glucocorticoids.

## Antihistamines.

The presence of histamine in the lower airways has been correlated with bronchial obstruction,[24] and histamine has long been thought to play a role in bronchial asthma. However, early studies of first-generation antihistamines in adolescents and adults showed minimal improvements in bronchial asthma, and initial small trials of second-generation antihistamines yielded mixed results.[25,26] However, two recent large-scale clinical studies using an antihistamine alone and an antihistamine-decongestant combination both resulted in significant improvements in asthma control. Grant and colleagues[27] demonstrated that seasonal symptoms of rhinitis and asthma were significantly attenuated in patients treated with cetirizine 10 mg once daily in a large group of adolescents and adult patients. In a second study using loratadine 5 mg plus pseudoephedrine 120 mg twice daily in patients with seasonal allergic rhinitis and asthma, Corren and colleagues[28] demonstrated that asthma symptoms, peak expiratory flow rates, and $FEV_1$ were all significantly improved in patients taking active therapy. In reviewing data from these and similar trials, it is difficult to determine whether the salutary effects of antihistamines in asthma can be attributed to direct effects on lower airway physiology or to improvements in rhinitis. Because many of the currently available agents appear to have weak or transient effects on resting airway tone, benefits to the lower airway may be due to modulation of upper airway function.

In the nested case-control study of rhinitis therapy and asthma outcomes, the use of second-generation oral antihistamines was associated with a nonsignificant trend toward lower risk of asthma-related emergency room visits and hospitalization.[21] However, there appeared to be a possible additive effect between second-generation antihistamines and INS in further lowering the probability of a major asthma-related event.

These studies demonstrate that treatment of rhinitis may result in improvements in a number of asthma outcomes and suggest that nasal disease contributes to the pathophysiology of asthma. Based on the data in these studies, treatment of rhinitis may reduce symptoms of mild asthma to such an extent that the requirement for asthma therapy may be reduced or even eliminated. While population-based analyses have also shown that major asthma exacerbations resulting in hospital care may be reduced by INS, these findings reflect an important association but do not prove cause and effect.

## Pathophysiologic Connections Between Allergic Rhinitis and Asthma

Although there is increasing evidence that allergic rhinitis may influence the clinical course of asthma, the mechanisms connecting upper and lower airway dysfunction are not entirely understood. A variety of theories have been invoked, including both direct and indirect effects of nasal dysfunction on the lower airways.

### Systemic Effects of Nasal Inflammation on the Lower Airways

Research over the past few years has demonstrated that several inflammatory mediators produced during allergic reactions may enter the systemic circulation. Experimental nasal allergen challenge has been shown to induce both peripheral blood eosinophilia[29] and activation of peripheral blood leukocytes.[30] It has been postulated that the net result of these various factors on the systemic circulation is the promulgation of inflammation in other sites. Braunstahl and colleagues performed a nasal provocation study, suggesting a link between systemic inflammation and changes in airway inflammation and function.[29] Prior to and 24 hours after the nasal challenge, bronchial mucosal biopsies were performed that demonstrated that the number of eosinophils in the lower airway mucosa, as well as the expression of adhesion molecules, increased after nasal allergen challenge. Further supporting this interaction between the upper and lower airways, Braunstahl and colleagues[31] also found increased inflammatory markers in the nasal mucosa following the instillation of allergen into the lower airways of subjects with allergic rhinitis. Given this emerging evidence, it is likely that systemic factors do play a critical role in the interaction between the upper and lower airways.

### Impaired Mucosal Function

It has been shown that allergic inflammation in the respiratory mucosa results in impairment of the barrier function of the epithelium.[32] It has been hypothesized that this alteration in epithelial integrity might then lead to increases in allergen uptake, synthesis of IgE, and ultimately involvement of the lower airways. Alternatively, impaired nasal mucosa may be more susceptible to viruses, resulting in an increase in allergic sensitization and subsequently more asthma (Fig. 47.1).[33]

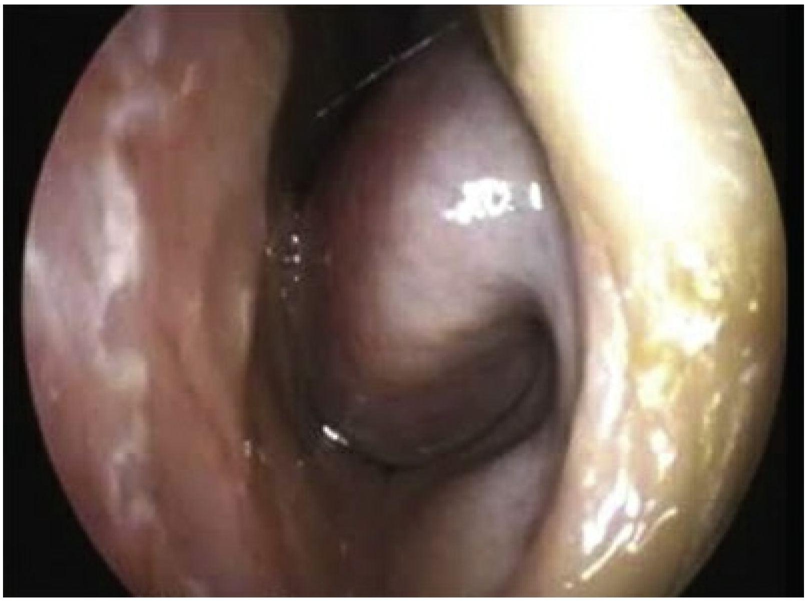

**FIG. 47.1** Pale mucosa and clear secretions in child with allergic rhinitis.

## Nasal-Bronchial Reflex

Early mechanistic studies investigated the effects of several mucosal irritants on lower airway function in normal human subjects. In 1969, Kaufman and Wright[34] applied silica particles onto the nasal mucosa of individuals without lower airway disease and noted significant, immediate increases in lower airway resistance. Bronchospasm induced by nasal silica was blocked by both resection of the trigeminal nerve[35] and systemic administration of atropine. Fontanari and coworkers[36] recently reevaluated the possibility of a neural connection between the upper and lower airways by using cold, dry air as the nasal stimulus. These investigators demonstrated that nasal exposure to very cold air caused an immediate and profound increase in pulmonary resistance that was prevented by both topical nasal anesthesia and cholinergic blockade induced by inhalation of ipratropium bromide. Both these studies strongly suggest the presence of a reflex involving irritant receptors in the upper airway (afferent limb) and cholinergic nerves in the lower airway (efferent limb).

Subsequent studies used challenge materials considered to be more biologically relevant to allergic rhinitis, including histamine, whole pollen particles, and allergen extracts. Yan and Salome[37] performed nasal histamine challenges in subjects with perennial rhinitis and stable asthma and observed that $FEV_1$ was reduced by 10% or more immediately after provocation in 8 of 12 subjects. Importantly, radiolabeling studies were performed as part of this study that demonstrated that histamine was not deposited into the lower airways. However, other studies that used histamine[38] or allergen[39] failed to demonstrate bronchoconstriction after nasal provocation. This discrepancy in results may be partly explained by the type of patients who participated in these studies. Whereas Yan and Salome[37] investigated subjects with perennial, symptomatic nasal disease, the majority of other studies examined asymptomatic patients outside their pollen season. Certainly, a substantial degree of heterogeneity exists between patients in their lower airway response to nasal stimulation.

In addition to neurally mediated bronchospasm, it has been postulated that a nasal allergic reaction might result in an alteration in lower airway responsiveness. Corren and colleagues[39] investigated the effects of nasal allergen provocation on nonspecific bronchial responsiveness to methacholine. Ten subjects with seasonal allergic rhinitis and asthma were selected for study; all patients related worsening of their asthma to the onset of hay fever symptoms. Nonspecific bronchial responsiveness was significantly increased 30 minutes after nasal challenge and persisted for 4 hours.

Because radionuclide studies demonstrated no evidence of allergen deposition into the lungs, it seems unlikely that these increases in airway reactivity can be attributed to direct effects of allergen. In addition, the rapidity with which these changes occurred suggests the possibility of a reflex mechanism.

### Mouth Breathing Caused by Nasal Obstruction

Nasal blockage resulting from tissue swelling and secretions may cause a shift from the normal pattern of nasal breathing to predominantly mouth breathing. Previous work has shown that mouth breathing associated with nasal obstruction resulted in worsening of exercise-induced bronchospasm, whereas exclusive nasal breathing significantly reduced asthma after exercise.[40] Improvements in asthma associated with nasal breathing may be the result of superior humidification and warming of inspired air before it reaches the lower airways.[41] Similarly, it would be expected that airborne allergens and pollutants would also be less likely to enter the lungs during periods of normal nasal function.

### Postnasal Drip of Inflammatory Material

Patients frequently complain that postnasal drip triggers episodes of coughing and wheezing. Early studies investigating the possibility of aspiration of nasal secretions demonstrated that substances placed in the upper respiratory tract could later be recovered from the tracheobronchial tree.[42] More recently, Huxley and colleagues[43] investigated pharyngeal aspiration during sleep both in healthy subjects and in patients with depressed sensorium. With the use of a radiolabeled marker that was intermittently released into the nose, pulmonary aspiration was detected in a significant number of both the normal and the ill subjects. In a more recent and definitive investigation, however, Bardin and colleagues[44] were unable to document significant aspiration of radionuclide in a study of 13 patients with chronic rhinosinusitis (CRS) and asthma.

It is difficult to determine which of these experimental mechanisms is most important in linking the nose to the lower airways. In all likelihood, however, several of these phenomena may contribute in some way to alterations in lung physiology in patients with allergic rhinitis and asthma.

## Diagnostic and Therapeutic Implications

### Diagnosis

The previously discussed data suggest that all patients with asthma be evaluated to determine the presence of concomitant chronic rhinitis. The patient should be questioned regarding types of symptoms, focusing on the presence of nasal congestion, sneezing, itching, discharge, and postnasal drip. Other associated symptoms (e.g., snoring, poor sleep quality, and ear congestion or popping) should also be investigated and considered when choosing therapy. The upper airway should then be carefully examined, with an emphasis on the size and vascularity of the nasal turbinates, type and presence of nasal secretions, tonsillar size, and color and elasticity of the tympanic membranes.

While allergic rhinitis is the most common form of chronic rhinitis in children (older than 2 years of age) and adolescents, a smaller number of patients will have chronic nonallergic rhinitis or CRS without allergy as the cause of their symptoms (Table 47.1). Some children with CRS have concomitant allergy and may have symptoms and signs of both conditions. Much less likely is the possibility of a structural problem resulting in obstruction. In children, this is most likely to be a foreign body, such as a peanut or small piece of toy, which is inserted into the nose and causes unilateral nasal blockage and discharge with sneezing; occasionally, this is followed by a secondary sinus infection. Bony or cartilaginous problems (such as a deviated nasal septum) are unusual and most likely the result of trauma.

**Table 47.1**

**Differential Diagnosis of Chronic Nasal Symptoms in Children**

| | Allergic Rhinitis | Nonallergic Rhinitis | Chronic Rhinosinusitis |
|---|---|---|---|
| Nasal congestion | Mild-severe | Usually severe | Mild-severe |
| Sneezing | Mild-severe | None | None |
| Pruritis | Mild-severe | None | None |
| Watery discharge | Mild-severe | Mild-severe | None |
| Purulent discharge | None | None | Mild-severe |
| Eye symptoms | Mild-severe | None | None |
| Periorbital darkening | Mild-severe | Mild-severe | Mild-severe |
| Headache/pressure | None-mild | None-mild | Mild-severe |

Regarding diagnostic testing in patients with persistent rhinitis and asthma, allergy skin tests or *in vitro* measures of specific IgE should be performed using a panel of common airborne allergens.

At a minimum, these should include house dust mites (*Dermatophagoides farinae* and *D. pterynissinus*), cockroaches, animal dander types (cat and dog), indoor and outdoor molds *(Penicillium, Aspergillus, Cladosporium, and Alternaria),* and regional pollens. This information is critical in differentiating allergic rhinitis from nonallergic disease or CRS and establishing an appropriate program of environmental control measures. Other tests, including total serum IgE level, microscopic analysis for nasal cytology, and total circulating blood eosinophils, have not proven helpful in either differentiating allergic rhinitis from other nasal disorders or in assessing the severity of the problem.

## Allergen Avoidance

Once allergy testing is complete, the physician may devise a comprehensive program of allergen avoidance. The effects of environmental control strategies have been most heavily studied regarding dust mites and furry pets (Box 47.1).[45] Compliance with these measures may be difficult, but they will certainly be helpful in many patients with hypersensitivity to these allergens.

**Box 47.1**

### Allergen Avoidance Strategies for Allergic Rhinitis

#### House Dust Mites

Weekly washing of all bedding in hot water (>130°F)
Weekly vacuum cleaning of all floor surfaces, using high-efficiency particulate air (HEPA)-type vacuum cleaner or standard vacuum cleaner with double-thickness reservoir bag
Removal of carpeting, or treatment of carpeting every 2–3 months with acaricidal spray or powder

#### Animal Danders (Any Furry Pet)

Optimal—Removal of the animal from indoor environment, followed by replacement of carpeting and aggressive housecleaning
Possibly effective—Keeping the cat indoors and instituting the following measures: Noncarpeted floors
Plastic or leather furniture
Frequent vacuum cleaning of floors
High-flow air filtration
Frequent cat bathing

### Indoor Mold

Thorough eradication of infestation
Repair of source of water intrusion

### Cockroach

Appropriate handling and storage of food and garbage

## Pharmacotherapy

While carefully designed allergen avoidance strategies may reduce symptoms to varying degrees, most patients will still require pharmacotherapy. In patients with persistent symptoms, particularly if nasal congestion is present, INS should be considered as first-line therapy. A large number of studies have established that there are no differences in efficacy between all the available compounds,[46] and most compounds (including budesonide, mometasone furoate, and fluticasone propionate) have been shown to have no significant effects on linear growth velocity in young children. These drugs should be used on a regular basis in patients with daily symptoms, or as long as symptoms dictate in children with intermittent problems.

Oral $H_1$ antihistamines have long been a mainstay of therapy for allergic rhinitis and are most effective in relieving sneezing, itching, and rhinorrhea, with minimal effects on nasal congestion. For this reason, they are often combined with oral decongestants, such as pseudoephedrine. Oral antihistamines that cause minimal or no sedation have been approved for use in young children, including cetirizine, fexofenadine, and loratadine.[47] Because they are available in a number of different formulations (i.e., tablets, rapidly dissolving pills, and liquids), patient preference may dictate choice of medication.

Montelukast, a leukotriene $D_4$ receptor antagonist, is also used for allergic rhinitis in children.[48] Montelukast has been shown to reduce all the symptoms of rhinitis, including nasal congestion. Because montelukast also has been shown to be effective in treating concomitant asthma, this medication may be very effective as a solo treatment for children with mild persistent allergic rhinitis and concomitant asthma.

## Specific Allergen Immunotherapy

Many children will continue to have persistent symptoms of rhinitis despite employing environmental control measures for indoor allergens and a combination of drugs, often including an intranasal corticosteroid with an antihistamine or montelukast. Occasionally, children may experience adverse effects that necessitate discontinuation of some or all their rhinitis medications. In these children, specific allergen immunotherapy should be strongly considered. Studies performed over the past decade have demonstrated that subcutaneous specific allergen immunotherapy to a wide range of allergens, including dust mites; cat dander; selected outdoor molds; and numerous grass, tree, and weed pollens; have had a high rate of clinical efficacy, with approximately 75% of children manifesting a good clinical response. Other studies have documented multiple salutary immunologic effects of immunotherapy, including a reduction in allergen-induced early- and late-phase allergic responses and attenuation of cytokine (e.g., Interleukin-4) production. An important potential benefit of immunotherapy is its effect on progression of allergic airway disease. A recent large prospective study in children with seasonal allergic rhinitis demonstrated that a 3-year course of subcutaneous immunotherapy (SCIT) reduced the development of asthma symptoms and improved bronchial responsiveness compared with an open control group.[49] In a follow-up of this group 7 years after stopping SCIT, 24 of 53 (45%) children treated with a placebo had developed asthma, compared with 16 of 64 (25%) who received active immunotherapy, representing a 44% reduction in asthma cases.[50] Regarding duration of treatment, once initiated, SCIT should be continued for at least 3 years.

More recently, investigators have turned their attention to other modes of administering allergen immunotherapy to both children and adults, particularly sublingual immunotherapy (SLIT). In a meta-analysis of clinical trials of SLIT in children with allergic rhinitis and asthma, SLIT caused a significant reduction in both symptoms (SMD −1.14; 95% CI, −2.10 to −0.18; $P = 0.02$) and medication use (SMD −1.63; 95% CI, −2.83 to −0.44; $P = .007$).[51] SLIT does have advantages compared with SCIT, including the absence of a buildup phase, fewer systemic reactions, and the convenience of home administration. However, it is unknown whether SLIT is as effective as SCIT, whether the effects are sustained after stopping treatment, and whether it can prevent the development of lower airway disease. Future trials will be essential in answering these questions.

Given the ability of SCIT to cause long-term modifications in nasal allergic disease as well as reduce the risk of developing asthma, allergen immunotherapy should be a strong consideration in all children with moderate to severe allergic rhinitis.

## Summary

Allergic rhinitis is virtually ubiquitous in children with asthma that is frequently underidentified and undertreated. In adolescents, allergic rhinitis may in fact serve as a risk factor for developing asthma. INS appear to significantly modulate lower airway reactivity and have been shown in a number of small studies to have beneficial effects on mild asthma. Current research suggests that the upper and lower airways are most importantly connected via the systemic circulation, which likely distributes products of inflammation throughout the respiratory tree. Allergic rhinitis should always be considered in patients with asthma and should be treated aggressively once it has been identified. Immunotherapy may be particularly useful in children with allergic rhinitis and new-onset asthma, because it may modify the long-term prognosis of their airway disease.

# Chronic Rhinosinusitis and Asthma

## Epidemiologic Relationship Between Chronic Rhinosinusitis and Asthma

Since the early 20th century, physicians have noted that CRS and asthma frequently coexist in the same patients. In 1925, Gottlieb[52] noted that 31 of 117 adolescent and adult patients with asthma suffered from severe symptoms of CRS. Other investigators reported similar findings in both children and adults during the next decade, with an incidence of symptomatic CRS as high as 72% in patients with asthma.[53] Conversely, a large retrospective study of pediatric, adolescent, and adult patients with CRS noted a 12% incidence of asthma,[54] and only one-third of the patients with both sinus disease and asthma in this study reported that CRS preceded their lower airway symptoms.

Attempts to define the incidence of sinus disease in patients with asthma again lay dormant until the early 1970s. These more recent reports have emphasized the role of radiography in diagnosing CRS. Several studies have demonstrated that 31%–53% of asthmatics across all age groups have abnormal sinus radiographs, with 21%–31% of patients demonstrating significant findings (defined as opacification of one or both maxillary sinuses, air-fluid levels, or mucosal thickening >5 mm).[55–58] In a more recent study that examined the utility of sinus computed tomography (CT) scanning in children with asthma, 58% of the children studied had varying abnormalities of all of the sinuses (Table 47.2).[59]

**Table 47.2**

**Prevalence of Radiographic Sinusitis in Asthmatics**

| Study | Sample Size | Age Range (Years) | Total Abnormalities (%)[a] | Significant Abnormalities (%) |
|---|---|---|---|---|
| Berman et al.[55] | 52 | 19–80 | 62 | NA |
| Rachelefsky et al.[56] | 70 | 3–16 | 52 | 27 |
| Schwartz et al.[57] | 217 | 9–70 | 47 | 21 |

|  |  |  |  |  |
|---|---|---|---|---|
| Zimmerman et al.[58] | 138 | 6–19 | 31 | 31 |
| Chen et al.[59] | 53 | 4–14 | 58 | NA |

[a]Opacification, air-fluid level, or >5 mm mucosal thickening.

*NA*, Not assessed.

Although the incidence of radiographic sinus abnormalities is universally high in asthmatics, others have questioned whether these changes have clinical significance. Fascenelli[60] prospectively performed sinus radiography on 411 asymptomatic normal adolescent and adult male volunteers and noted a 28% incidence of maxillary sinus abnormalities. Most of these changes, however, consisted of minimal thickening, and only 5% of the group demonstrated significant thickening (>5 mm) of the maxillary antrum. In a similar prospective study of young children, Kovatch and colleagues[61] noted that 8 of 22 (36%) asymptomatic children younger than 1 year of age demonstrated either thickening greater than 4 mm or opacification of the maxillary sinuses. Only 2 of 31 (6%) children older than 1 year of age, however, demonstrated these same changes. These two studies demonstrate that it is unusual to detect significant radiographic abnormalities of the maxillary sinuses in normal, healthy individuals older than 1 year of age. Significant abnormalities of sinus radiographs are much more common in patients with asthma than in healthy, nonasthmatic individuals, suggesting that these radiographic findings most likely reflect pathologic changes of the sinus tissue rather than radiologic artifact.

# Unique Features of Chronic Rhinosinusitis in Asthmatics

## Clinical Features

CRS in children is often an indolent illness, usually characterized by the following cardinal symptoms: nasal congestion, purulent anterior or posterior nasal drainage, and cough.[62] Several other symptoms are reported by patients with CRS, including fatigue, malaise, cough, sleep disturbance, ear pain or pressure, dizziness, halitosis, dental pain, dysphonia, or nasal or throat irritation. However, none of these is specific enough to be clinically useful in diagnosis.

Although headache and facial fullness may also be prominent complaints in adults, it is uncommon in children with CRS. While fever may occasionally be observed in patients with acute sinusitis, it is rarely seen in chronic disease. Because cough may be the most prominent presenting symptom of CRS in children, the physician must maintain a high index of suspicion regarding this possibility. Therefore, any child with symptomatic asthma and cough who has responded poorly to conventional asthma treatment (e.g., inhaled corticosteroid plus a long-acting $\beta_2$ agonist, a leukotriene $D_4$ receptor antagonist, or both) and has persistent nasal symptoms should be evaluated thoroughly for chronic sinus disease.

Physical findings usually include nasal swelling, dried purulent secretions, and occasionally shiners (periorbital darkening) (Figs. 47.2 and 47.3).

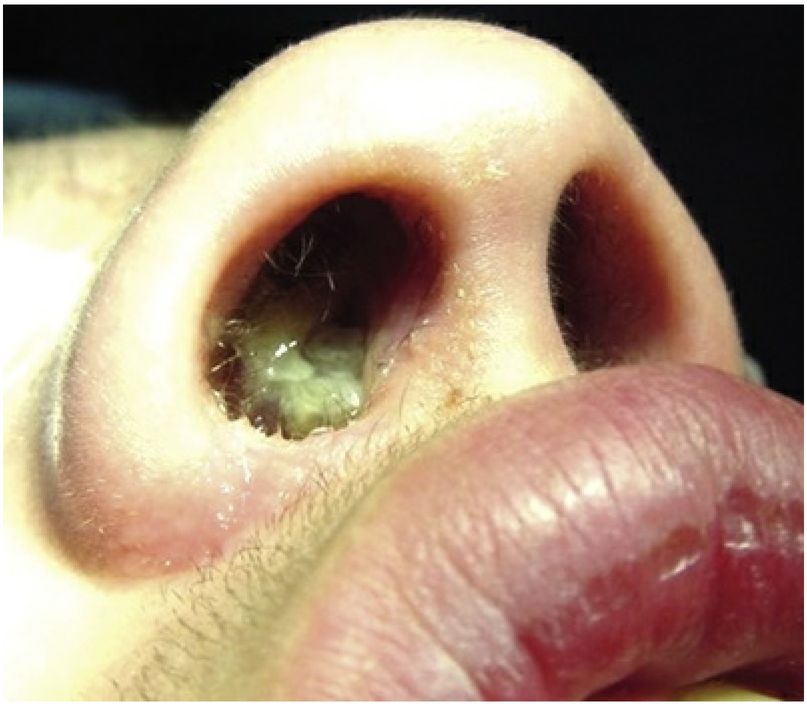

**FIG. 47.2** Purulent secretions in child with chronic rhinosinusitis.

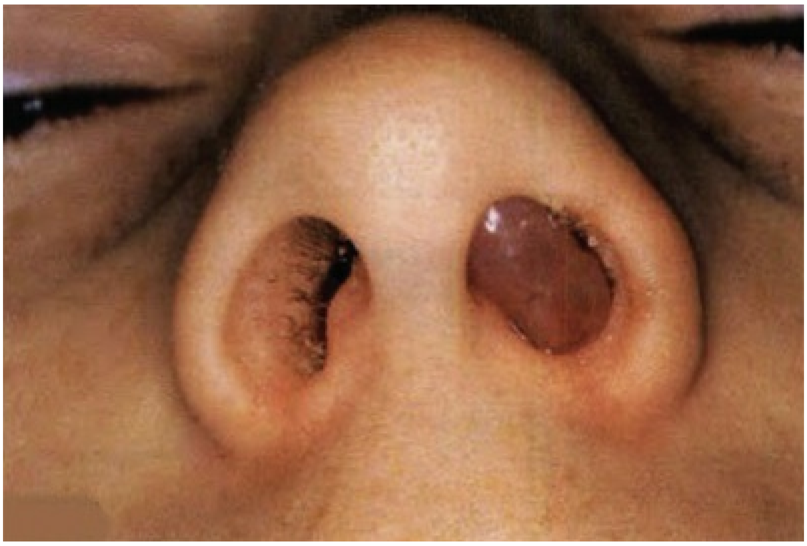

**FIG. 47.3** Nasal polyp in child with chronic rhinosinusitis.

### Chronic Rhinosinusitis With Nasal Polyps.

Nasal polyps (NP) represent inflammatory masses that originate in the paranasal sinuses of patients with CRS and evaginate into the nasal airway. CRS with NP (CRS/NP) is seen most commonly in adult patients and is unusual in young children. NP are present in approximately 0.1% of unselected children in the United States,[63] but the vast majority are diagnosed in children with cystic fibrosis[64] and allergic fungal rhinosinusitis. In children with asthma, the exact prevalence of NP is not known, but in patients diagnosed with NP, roughly one-third have concomitant asthma.[65] Therefore, when polyps are visualized in children, the clinician should suspect that the patient may also have asthma and should always consider the possibilities that the child may have underlying cystic fibrosis or allergic fungal sinusitis (AFS) (Fig. 47.4).

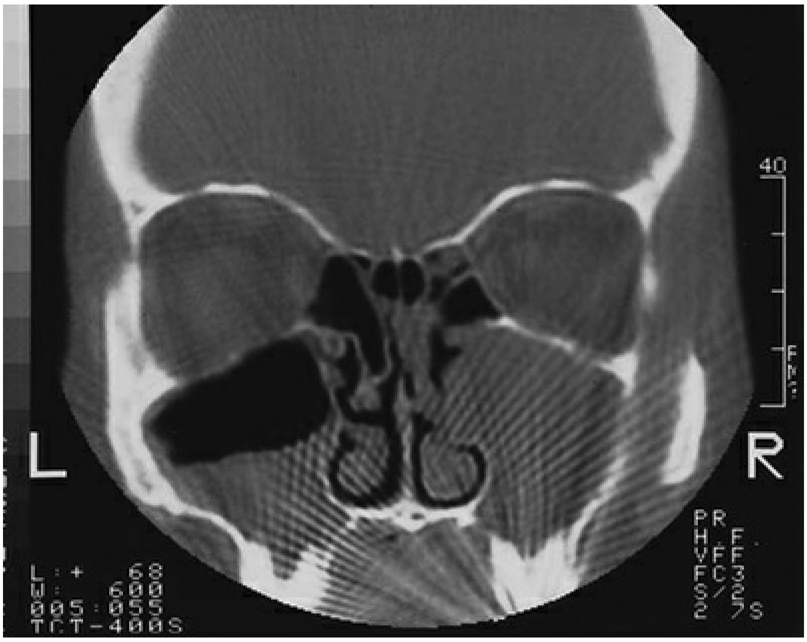

**FIG. 47.4** Sinus computed tomography of child with chronic rhinosinusitis.

## Histopathology

Most studies of sinus histopathology have historically been performed in adult patients, and only in the past 20 years have investigators carefully examined the sinus mucosa of children with CRS. A study of children with CRS were compared regarding the concomitant presence of asthma ($n = 13$), cystic fibrosis ($n = 10$), or neither ($n = 11$).[63] More eosinophils were counted in the sinus tissues of patients with asthma and cystic fibrosis compared with patients without concomitant disease, but this did not reach statistical significance, most likely as a result of very small sample sizes. In addition, allergy status (as defined by skin testing) did not affect the degree of tissue eosinophilia. A small number of other studies confirm that children with CRS but without asthma have low numbers of sinus mucosal eosinophils. The above studies suggest that the sinus mucosa in children with CRS and asthma may have a similar histologic profile to the sinuses of adult patients with CRS and asthma and that eosinophils play a potential role in the pathogenesis of both their sinus and lower airway diseases.

## Microbiology

In 1974, Berman and colleagues[55] studied 21 adolescent and adult patients with asthma and radiographic abnormalities of the maxillary sinuses. Bacterial cultures of sinus aspirates demonstrated positive bacterial growth in only 5 of 25 aspirates. Eighty percent of the subjects in this study, however, had minimal evidence of sinusitis (mucosal thickening <2 mm and no sinus polyps). Therefore, conclusions from this study are most relevant to patients with mild sinusitis and may not be applicable to individuals with evidence of more severe disease. In children with asthma and CRS, several bacteriologic studies have been conducted. In 1983, Adinoff and colleagues[67] published a report regarding 42 asthmatic children with sinusitis. Only 12% of maxillary sinus aspirates had positive bacterial cultures; however, many of the studies involving children showed only mild radiographic abnormalities with <5 mm mucosal thickening. Friedman and colleagues[68] in 1984 and Goldenhersh and colleagues[69] in 1990 performed maxillary aspirates in groups of 8 and 12 asthmatic children, respectively, with significant radiographic evidence of sinusitis (i.e., opacification, air-fluid levels, or mucosal thickening >5 mm). These two groups demonstrated that 60% and 75% of these children, respectively, had positive bacterial cultures, and the organisms were the same as those found in acute sinusitis, including *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.* Taken together, the above studies demonstrate that the majority of children with sinusitis and asthma appear to have a chronic inflammatory disease of the sinus mucosa that is prone to persistent infection with predominantly aerobic bacteria. Data from the radiographic studies also suggest that minor degrees of mucosal inflammation observed on sinus radiograph are usually not associated with active bacterial infection.

## Allergic Fungal Sinusitis

An unusual type of chronic sinusitis in children is caused by an allergic reaction to fungi, referred to as AFS. A recent retrospective review characterized 20 children and adolescents (7–18 years of age) with AFS and determined that 90% had NP, 55% had a prior history of asthma, and 50% had proptosis. Laboratory analyses revealed that all patients had abnormal sinus CT findings and positive skin tests to fungi, 90% had an elevation of total IgE, and 70% had peripheral eosinophilia.[70] Surgical specimens demonstrated allergic-type mucin in 55% of patients and positive fungal cultures in 85%. Importantly, relapse was seen in 55% of patients at 1-year follow-up.

## Effects of Sinus Therapy on Severity of Asthma

For the past century, otolaryngologists have cataloged the effects of sinus therapy on asthma symptoms. Because most of the earliest data were based on postsurgical observations, these studies are reviewed first.

### Surgical Treatment

In the early 20th century, physicians observed that surgical treatment of nasal and sinus disease resulted in variable improvements in asthma symptoms. In 1936, Weille[71] published his study of 500 asthmatic patients of varying ages, 72% of whom had chronic sinus disease. Following sinus surgery in 100 of the patients, 56 reported that their chest symptoms were improved, and 10 experienced complete resolution of asthma. Improvement in asthma symptoms, however, also occurred in 40% of the patients who did not undergo sinus surgery. In 1969, Davison[72] reported that 23 of 24 adolescent and adult patients with CRS and asthma experienced a 75% or greater improvement in asthma symptoms after surgical drainage of the sinuses. Werth[73] presented the results of sinus surgery in children, noting that 20 of 22 pediatric patients with severe asthma and sinusitis experienced a marked improvement in asthma after sinus surgery.

To date, there have been no randomized, controlled trials examining the effects of sinus surgery on lower airway symptoms or function. The study by Weille indicates that asthma symptoms may improve spontaneously in the absence of surgical intervention. Collectively, however, these reports suggest that long-term control of asthma symptoms may improve after surgical sinus procedures.

### Medical Treatment

During the past decade, multiple investigators have studied the effect of medical therapy for CRS on asthma symptoms, primarily in children. In 1981, Businco and colleagues[74] reported that 10 of 12 children with chronic asthma had an improvement in lower airway symptoms after medical therapy, although no objective measures of pulmonary function were performed. In 1983, Cummings and colleagues[75] performed a double-blind, placebo-controlled study of sinus therapy in asthma. Active treatment (i.e., antimicrobials, nasal steroids, and oral decongestants) of children with opacification or marked thickening of the maxillary sinuses resulted in significantly fewer asthma symptoms and a reduced requirement for inhaled bronchodilator and oral steroid therapy. Neither pulmonary function results nor measures of bronchial reactivity were significantly improved with active treatment. In 1984, Rachelefsky and colleagues[76] studied 48 children with a 3-month or longer history of sinusitis and wheezing. After 2–4 weeks of antimicrobials with or without antral lavage, 38 of the patients were able to discontinue daily bronchodilator therapy, and 20 of 30 patients demonstrated normalization of pulmonary function tests. More recently, Tsao et al. treated a group of 41 children with CRS and mild asthma with oral antibiotics (amoxicillin-clavulanate) for 6 weeks versus nasal saline irrigations for 6 weeks in an unblinded crossover trial.[68] Children treated with antibiotics experienced significant improvements in signs and symptoms of CRS. While $FEV_1$ did not change following antibiotic therapy, methacholine $PC_{20}$ increased significantly after treatment with amoxicillin-clavulanate for 6 weeks.

Similar to the surgical observations, these studies suggest that medical treatment of sinusitis may result in improvement of bronchial asthma. Although only one randomized, placebo-controlled trial has been performed, the literature shows that both chest symptoms and lower airway function improve after medical therapy.

## Pathophysiologic Links Between Chronic Sinusitis and Asthma

As noted in the section entitled Allergic Rhinitis and Asthma, a number of potential mechanisms may help explain the connection between upper and lower airway dysfunction. Specifically, with respect to the relationship between sinus inflammation and asthma, an animal model has provided some promising insights into this interaction. Brugman and colleagues[77] created an experimental model of sinus inflammation in rabbits using complement fragment C5a. Although induction of sterile sinus inflammation in rabbits caused no changes in baseline lung function, bronchial responsiveness to inhaled histamine was significantly increased. Because these changes could be prevented by strategies that blocked drainage of inflammatory exudates beyond the larynx, the researchers postulated that postnasal drip was most likely responsible for the alteration in airway reactivity. Importantly, however, there was no evidence of lower airway inflammation by either histologic examination or bronchoalveolar lavage. This association of hyperresponsiveness with morphologically normal airways is difficult to explain but again suggests the possibility of a neurally mediated response.

## Diagnostic and Therapeutic Implications

In children with moderate to severe asthma, chronic sinusitis should always be considered as a possible provocative factor. The clinical history and physical examination, however, are neither sensitive nor specific for chronic sinus disease. Therefore, we evaluate all children with poorly controlled or steroid-requiring asthma with a Waters' view (occipitomental) sinus radiograph, which is primarily useful for examining the maxillary sinuses. Although CT of the paranasal sinuses has proven to be considerably more sensitive than plain radiographs in detecting subtle mucosal disease,[78] plain radiographs maintain an important role as an initial imaging study. First, plain radiographs are simple, convenient, and relatively inexpensive to perform. Second, in contrast to CT imaging, plain radiographs do not require sedation in infants or young children. Finally, the significance of subtle sinus CT changes is unclear because such abnormalities may be present in up to 50% of children[79] who have no clinical evidence of either sinusitis or asthma. We reserve CT imaging of the sinuses for patients with clinical histories strongly suggestive of sinusitis who have normal plain radiographs and patients with persistent, severe sinus disease before surgical intervention.

Flexible fiberoptic rhinoscopy has been suggested as an alternative to plain radiographs because purulent drainage may be visualized in the vicinity of the middle and superior meatus.[80] This procedure does require sedation in young children, limiting its practical application in patients below the age of 8 years unless deemed medically necessary. In addition, there are diagnostic limitations of the procedure. The absence of visualized pus during the rhinoscopic examination does not rule out active infection, since sinus drainage may be obstructed by ostial edema or obstructing lesions of the nasal airway. Additionally, rhinoscopy will not detect significant hyperplastic changes in the sinuses, which may play an important pathogenic role in CRS.

Patients with well-defined symptoms of CRS or who demonstrate significant radiographic abnormalities of the maxillary sinuses (i.e., opacification, air-fluid levels, or thickening >5 mm, or more than 50% of the maxillary antrum) are treated with medical therapy. We classify medical treatment modalities for CRS into three categories: antimicrobials to eliminate possible concomitant infection, medications to reduce swelling, and measures to thin and evacuate secretions (Box 47.2).

### Box 47.2

## Pharmacotherapy for Allergic Rhinitis

| EXAMPLES | 2–5 YEARS | 6–11 YEARS |
|---|---|---|
| Loratadine | 5 mg QD | 10 mg QD |
| Cetirizine | 2.5–5 mg QD | 5–10 mg QD |
| Fexofenadine | 30 mg BID | 30 mg BID |
| Beclomethasone (40 μg/sp) | 1 sp QD | 1 sp QD |
| Budesonide (32 μg/sp) | NA | 2 sp QD |
| Fluticasone propionate (50 μg/sp) | 1–2 sp QD | Same |
| Fluticasone furoate (27.5 μg/sp) | 1 sp QD | Same |
| Mometasone furoate (50 μg/sp) | 1 sp QD | Same |
| Triamcinolone (55 μg/sp) | NA | 2 sp QD |

*NA,* Not applicable.

Because up to 25% of the bacterial isolates found in chronic sinusitis are β lactamase producers, we prescribe amoxicillin-clavulanate potassium as a first-line antimicrobial for a period of no less than 3 weeks. In children who are allergic to penicillin, clarithromycin is employed as an alternative. For nasal swelling, we often use topical decongestants (e.g., oxymetazoline) for the initial 3 days of therapy and continue oral decongestants (either phenylpropanolamine or pseudoephedrine) for an additional 7–10 days. If nasal swelling does not respond to these measures, we prescribe a 5- to 7-day tapering course of oral corticosteroids. All patients are also started on a topical nasal corticosteroid, which is usually continued on a long-term basis. We have found that evacuation of secretions, particularly dried crusts, is enhanced by performing nasal irrigations with saline or increasing humidification using a freestanding humidifier or hot shower. Nasal saline irrigations have been evaluated in a number of clinical trials, and a recent Cochrane review concluded that this treatment modality is helpful to patients with chronic sinusitis, either when used alone or as an adjunct to other treatments.[81] If patients fail to respond adequately to the aforementioned regimen, we obtain a sinus CT and refer them to an otolaryngologist for consideration of an endoscopically obtained sinus culture or possible surgery.

Regarding surgery for CRS in children, most experts suggest adenoidectomy for children with CRS and adenoidal enlargement who have not responded adequately to medical treatment (Box 47.3). The efficacy of adenoidectomy in this group of patients is uncertain but has been recommended by a 2014 consensus statement on CRS in children developed by an expert panel.[82] Favorable results are seen in some children in observational studies, but there are currently no available randomized trial data regarding the efficacy of adenoidectomy on either CRS or concomitant asthma.

**Box 47.3**

## Medical Treatment of Chronic Sinusitis in Asthmatics

### Antimicrobials

Amoxicillin-clavulanate potassium for 21 days (or clarithromycin in penicillin-allergic patients)

### Medications to Reduce Swelling

For severe swelling, topical oxymetazoline for 3 days
If swelling persists, continue with oral pseudoephedrine on a regular basis for 7–10 days or longer if needed
Intranasal corticosteroid spray for 3–6 weeks; consider long-term use
If swelling is severe and does not respond to above measures, prednisone 0.5 mg/kg body weight for 5 days, tapered over 3–5 days

### Measures to Enhance Evacuation of Secretions

Saline irrigations twice daily
Consider hot steam inhalations if mucus is tenacious and difficult to irrigate out of nose

If adenoidectomy is not helpful in reducing chronic nasal obstructive symptoms and reducing recurrent or chronic symptoms of sinusitis, endoscopic sinus surgery may be considered.[82]

## Summary

A great deal of data supports an association between chronic sinusitis and asthma. We have developed a better understanding of the pathogenesis of sinus disease in asthmatic patients and now realize that eosinophilic sinus infiltration plays a direct role in chronic mucosal inflammation that may predispose the paranasal sinuses to recurrent or chronic bacterial infection. Long-term blinded, placebo-controlled trials need to be completed before we can reliably predict the effect of sinus therapy on clinical asthma. Until then, we recommend that sinus disease be considered in all patients with moderate to severe asthma and treated aggressively when it is identified.

# Modern Molecular Therapies for Application in Managing Childhood Asthma

*Heather Ellen Hoch MD, William Carl Anderson III, MD, Stanley James Szefler MD* [a]

## Introduction

Attention in asthma management is now being directed toward the development of immunomodulators, medications that can potentially stimulate or impair features of the immune system. Based on current therapeutic strategies, the available medications, such as inhaled corticosteroids (ICS), long-acting β-adrenergic agonists, and leukotriene modifiers, have been shown to reduce asthma symptoms and exacerbations but have not been shown to alter the natural history of asthma. This review will focus on the class of immunomodulators, beginning with allergen immunotherapy (AIT) in its subcutaneous and sublingual forms, followed by experience with anti-IgE (omalizumab), and subsequently by recent experience with the introduction and evaluation of anti-IL5 and anti-IL4/13. Aside from AIT, the other immunomodulators have limited data in children. However, all of these agents hold promise in the possibility of altering the course of asthma, and further studies will be needed to assist the clinician in selecting these medications and the appropriate time for introduction in the management of children with asthma.

# Allergen Immunotherapy

## Indications and Patient Selection

AIT remains the only treatment modality available that can alter the natural course, and potentially have a curative approach in some patients, for asthma and other allergic conditions through its sustained disease-modifying effects.[1–3] The therapeutic preparation for AIT is extracted from source materials, such as pollen and animal pelts.[4] Two forms of AIT administration are currently in wide-scale clinical practice: subcutaneous immunotherapy (SCIT) and sublingual immunotherapy (SLIT). SLIT has been increasing in use over the last two decades, especially in Europe.[1,2] AIT is addressed both by the Global Initiative for Asthma (GINA) and National Institute of Health National Heart, Lung, and Blood Institute Expert Panel 3 (NIH NHLBI EPR-3) guidelines for the management of asthma when there is clear evidence between symptoms and exposure to an allergen to which the patient is sensitized.[5,6]

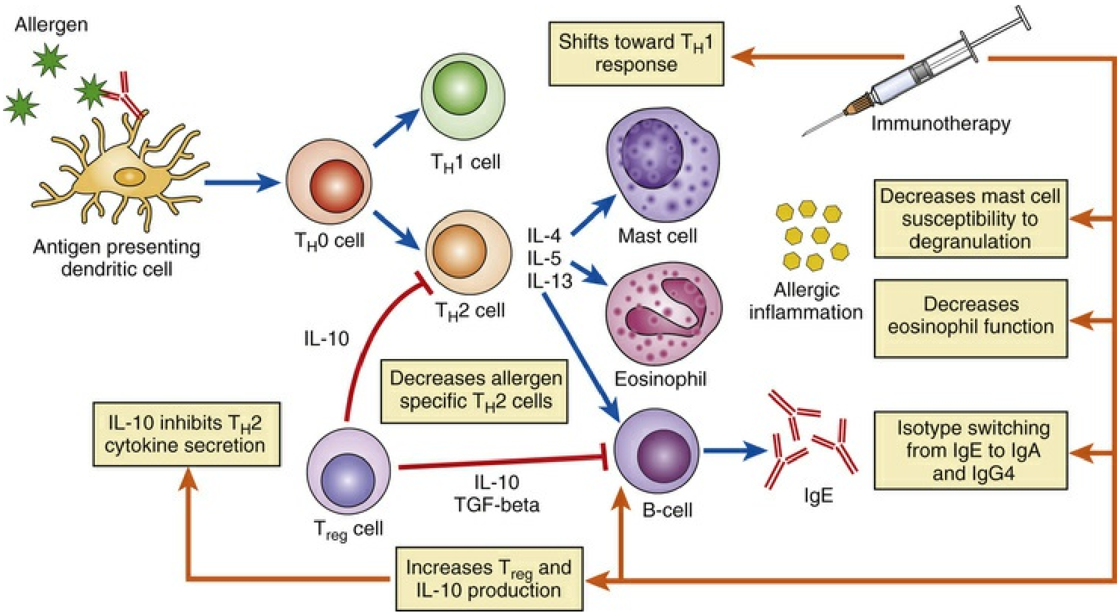
AIT should be reserved only for patients who have both documented evidence of sensitivity to an allergen, either through immediate hypersensitivity skin testing or in vitro testing for serum specific IgE antibodies, and symptoms that correlate with exposure to said allergen.[4] Skin-prick testing has been shown to have greater sensitivity than serum-specific IgE measurements based on nasal and bronchial challenge test results.[4] Patient-specific factors to consider when deciding whether to start AIT include the patient's preference, adherence, current medication requirements, level of asthma disease control, seasonality of disease, response to avoidance measures, medication adverse effects, coexisting allergic rhinitis, cost, impact on quality of life, and geographic location.[1,4,6] Patients whose symptoms are not well controlled by medications or avoidance measures, who are requiring multiple medications or high doses of medications to maintain asthma control, who may be experiencing side effects from their medications, or who wish to avoid long-term pharmacotherapy could be appropriate candidates for AIT.[4,6]

## Administration

SCIT may be administered via a conventional, cluster, or rush schedule. In conventional SCIT, the allergen is administered via once-weekly injections at increasing concentrations until a maintenance dose is achieved, followed by injections typically at 4-week intervals.[2,4] In a cluster schedule, multiple injections, usually 2–3, are administered on nonconsecutive days, while in a rush protocol, multiple injections are administered on consecutive days, allowing the patient to reach maintenance typically in 1–3 days.[2] As opposed to SCIT, SLIT's safety profile allows it to be administered with either a shortened or absent build-up phase.[2] A typical course of immunotherapy is 3–5 years in duration,[2,4,6] as studies with SCIT have demonstrated prolonged remission after 3–4 years of treatment.[7] Three years of SCIT may be sufficient in asthmatic children, as a prospective study did not show a significant clinical benefit, including change in asthma symptoms, ICS dose, quality of life, and bronchial hyperreactivity, from an additional 2 years of SCIT.[8] SLIT has a similar course, with its use for allergic rhinitis from house dust mites showing sustained remission for 7 and 8 years after 3 and 4–5 years of treatment, respectively.[9] The decision to stop or continue immunotherapy is based on the severity of the disease, benefits sustained from treatment, and convenience of treatment.[4]

## Mechanism of Action

The goal of AIT is to induce immune tolerance to specific allergens via downregulation of $T_H2$-mediated responses, through both induction of allergen-specific T regulatory ($T_{reg}$) cells and an ultimate shift toward a $T_H1$-mediated response (Fig. 48.1).[1,3,4,10]



Allergen
Antigen presenting dendritic cell
$T_H0$ cell
$T_H1$ cell
$T_H2$ cell
Shifts toward $T_H1$ response
Immunotherapy
IL-4
IL-5
IL-13
Mast cell
Eosinophil
Allergic inflammation
Decreases mast cell susceptibility to degranulation
Decreases eosinophil function
IL-10
Decreases allergen specific $T_H2$ cells
IL-10 inhibits $T_H2$ cytokine secretion
$T_{reg}$ cell
IL-10
TGF-beta
B-cell
IgE
Isotype switching from IgE to IgA and IgG4
Increases $T_{reg}$ and IL-10 production

**FIG. 48.1** The impact of immunotherapy on allergic inflammation. Immunotherapy shifts the immune response to an allergen from a $T_H2$ to a $T_H1$ pathway. Through the induction of immunosuppressive $T_{reg}$ cells producing IL-10 and TGF-beta, immunotherapy inhibits $T_H2$ cell cytokine secretion. Ultimately these changes decrease downstream induction of $T_H2$-mediated inflammation. *IL*, Interleukin; *TGF*, transforming growth factor.

Very early into the course of AIT desensitization, mast cells and basophils bearing the high-affinity IgE receptor, FcεRI, decrease their susceptibility to degranulation in response to the specific allergen.[1,10] With continued AIT desensitization, the proportion of IL-4-secreting $T_H2$ cells decreases, while $T_{reg}$ cells for the same allergic epitope increase in number and function.[1,4,10] These inducible CD4+CD25+ $T_{reg}$ cells secrete IL-10 and transforming growth factor beta (TGF-β), regulatory cytokines that function to mediate allergen-specific peripheral T-cell tolerance.[1,10,11] IL-10 directly inhibits T-cell cytokine production, including IL-4 and IL-5 by $T_H2$ cells, through suppression of the CD28 costimulatory pathway.[4,11] Cytokine production is also inhibited by IL-10 through the inhibition of the costimulatory molecules CD80 and CD86 on antigen-presenting cells, which eliminates the ability of these cells to provide the accessory signals necessary for T helper cell activation.[11]

IL-10 has regulatory effects on B-cells, mast cells, and eosinophils. IL-10 acts on B-cells to decrease antigen-specific IgE production and undergo class switching with IgG4 production.[1,4,10] Allergen-specific IgG4 competes with allergen-specific IgE for allergen binding, thus preventing the IgE-mediated release of inflammatory mediators from mast cells and basophils.[1,4,10] The binding of allergens to IgG4 also inhibits IgE-facilitated allergen presentation to T-cells.[1,4] In addition to the IgG4 isotype switching, TGF-β produced by $T_{reg}$ cells will induce the production of IgA at mucosa surfaces, which will also compete with IgE for allergen binding.[1,4,11] Allergen-specific IgE levels often transiently increase after AIT but then gradually decrease with continued treatment late into the AIT course, likely secondary to IL-10 and $T_{reg}$ cells.[1,4] Acting on mast cells, IL-10 and $T_{reg}$ cells modulate the threshold for mast cell activation, decrease IgE-mediated histamine release, and inhibit FcεRI-dependent mast cell degranulation.[1,4] IL-10 also downregulates eosinophil function, proinflammatory cytokine release, and activity.[1,4,10]

## Impact on Asthma Control

Meta-analyses of randomized controlled trials using SCIT to treat asthma in children and adults have demonstrated a significant reduction in asthma symptoms, asthma medication use, and allergen-specific and nonspecific bronchial hyperreactivity.[12,13] The effect on lung function has been mixed in these studies, with one meta-analysis showing no consistent effect on lung function,[12] while another showed an improvement in peak expiratory flow rates.[13] Specific individual studies in children have demonstrated similar results with improvement in asthma symptom-medication scores with the use of SCIT,[14] medication use,[15] decreased allergen-specific bronchial hyperreactivity when used in combination with ICSs,[14,16] and improvement in peak expiratory flow rates.[17]

Meta-analyses of randomized controlled trials examining the impact of SLIT on the treatment of asthma in children and adults have been limited in their ability to draw such significant conclusions as seen with SCIT, primarily secondary to wide but varied use of largely unvalidated symptom and medication scores, and significant heterogeneity between studies.[3,4,18,19] Meta-analyses examining symptom and medication scores in both pediatric and adult patients with both asthma and comorbid allergic rhinitis treated with SLIT have demonstrated a consistent reduction in combined asthma and allergic rhinitis symptom and medication scores, but differing results regarding its ability to impact asthma symptoms and medication use alone.[19,20] There is evidence that the benefit of SLIT for asthma may be more impactful in the pediatric than adult population. A meta-analysis investigating the use of SLIT exclusively in pediatric patients with allergic asthma as young as 3 years old showed a significant reduction in both asthma symptom scores and rescue medication use compared with placebo.[21] In a real-life randomized open controlled trial of SLIT in patients with allergic rhinitis with or without asthma, the use of SLIT compared with conventional medical therapy alone showed a significantly more pronounced reduction in combined rhinitis and asthma symptoms scores in patients less than 18 years of age than in adults.[22] Studies in children and adults have demonstrated a decrease in the number of patients with a positive methacholine challenge in those treated with SLIT in addition to standard medical therapy, versus those without SLIT.[22,23]

Most important would be SCIT and SLIT's ability to reduce ICS doses, especially in a pediatric population. Randomized trials of adults, adolescents, and pediatric patients with mild and moderate persistent allergic asthma have demonstrated that the addition of house dust mite SCIT and SLIT to ICSs resulted in a reduction in ICS dose while still maintaining asthma control.[17,24] Post hoc analysis of adolescent and adult patients treated with house dust mite SLIT with more severe disease, represented by only partly controlled asthma and higher ICS dose, demonstrated a greater significant impact on asthma control, ICS reduction, and quality of life than the less severe population.[25] In a trial of adults with house dust mite allergy–related asthma poorly controlled on ICSs or combination therapy, the addition of house dust mite SLIT increased the time to first moderate or severe asthma exacerbation during an ICS reduction period compared to placebo.[26]

## Persistent Clinical Effects After Discontinuation

AIT's ability to have persistent effects on asthma control or even resolution of the disease (stemming from its alteration of the underlying immunological response long after discontinuation of therapy) separates it uniquely from other therapies. A prospective study using house dust mite SCIT in asthmatic children showed that 3 years after discontinuation of SCIT, more than 50% of treated patients had remission of their asthma, compared with 3.3% of controls.[8] Patients treated with SCIT had significantly reduced doses of ICSs, lower asthma symptom scores, higher quality-of-life scores, less bronchial hyperreactivity, and higher forced expiratory volume in 1 second ($FEV_1$) compared with controls at the 3-year time mark.[8] Some of the impact of SCIT in childhood persists into adulthood, as demonstrated by a retrospective study that showed 9 years after the discontinuation of therapy, that asthmatic children who were not treated with SCIT had a three times higher risk of frequent asthma symptoms than those treated with house dust mite or grass pollen SCIT.[27] This study, however, did not show any difference in lung function or medication use between the groups 9 years after discontinuation of SCIT.[27] Similar findings have been demonstrated with the use of house dust mite SLIT in asthmatic children, with a reduction in the presence of asthma, number of patients using asthma medications, use of bronchodilator, and peak expiratory flow rate 5 years after the discontinuation of SLIT compared with controls.[28]

## Prevention of Asthma and Allergic Sensitivity Development

Perhaps the most profound effect of AIT is its ability to prevent progression of allergic sensitization and the development of asthma in children with allergic rhinoconjunctivitis.[4] Treatment with both

SCIT[15,29,30] and SLIT[23] against house dust mite, grass, and birch in monosensitized children with allergic rhinoconjunctivitis with or without asthma for 3 years has been shown to prevent or reduce the development of new aeroallergen sensitizations. The preventative effects of SCIT in the development of new aeroallergen sensitizations has been observed even 12 years after the discontinuation of therapy.[31]

The use of SCIT in children with seasonal allergic rhinoconjunctivitis to grass and/or birch pollen without asthma for 3 years in a randomized open trial resulted in significantly fewer patients developing asthma or having asthma symptoms after 3 years of treatment compared with controls,[32] with the preventative effect persisting at 2 years[33] and 7 years[34] after discontinuation of SCIT. Similar prevention of the development of asthma in children with allergic rhinoconjunctivitis has been demonstrated with the use of SLIT to dust mites, grasses, or birch for 3 years in addition to standard medical therapy, compared with medical therapy alone.[23,35] Those children who had bronchial hyperresponsiveness with allergic rhinoconjunctivitis[34] or who were younger[35] at baseline were most at risk of developing asthma, suggesting a potential benefit of the initiation of AIT in these groups for the prevention of asthma.

## Safety

According to the GINA, the benefits of AIT compared with other pharmacologic and avoidance options must be weighed against several factors, including the risk of adverse events.[2,5] SCIT carries the risk of localized injection site reactions, large local reactions, anaphylaxis, and even death.[36] Annual survey reports show the rate of a severe reaction of any severity is 11.8 reactions per 10,000 injection visits, with the rate of a severe life-threatening reaction being 0.1 reactions per 10,000 injection visits.[36] Overall, 95% of reactions were only mild to moderate in severity.[36] SCIT meta-analysis data estimated the risk of a near-fatal injection was once per 1 million injections and a fatal injection to occur once per 2.5 million injections.[12] Patients with severe or uncontrolled asthma are at increased risk for systemic reactions to SCIT, including fatal and near-fatal reactions, secondary to bronchoconstriction.[36,37] As such, poorly controlled asthma is a major contraindication to AIT.[2,4] Given the risk of these reactions, practice parameters recommend that SCIT only be administered in a supervised medical facility by a professional trained in the prescribing and administration of SCIT and patients be monitored for 30 minutes following the injection, as the risk of a life-threatening anaphylactic reaction after 30 minutes is rare.[1,4]

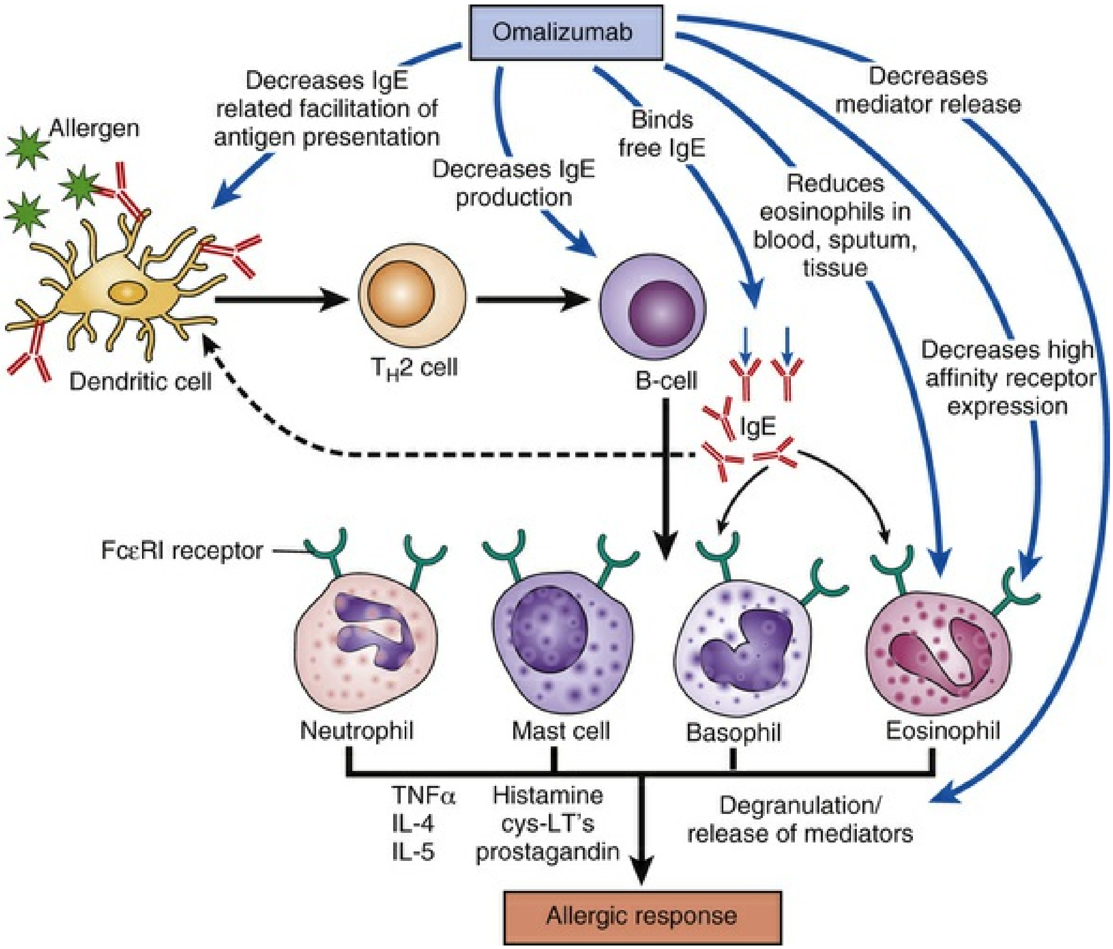
Unlike SCIT, the safety of SLIT is far superior, with no confirmed reports of SLIT-related fatalities to date, but anaphylactic reactions have been reported.[1,2,4,38] A comprehensive review showed the risk of a severe reaction to SLIT was 1.4 events per 100,000 doses.[39] The most common adverse reactions for SLIT are typically localized oral-mucosal pruritis or mild local edema, which occur within the first 30 minutes of administration, resolved spontaneously, and did not persist with continued therapy.[1,4,19] SLIT's favorable safety profile allows administration outside of a supervised medical setting.[2]

**Clinical Application.** AIT offers the potential for remission of disease activity but requires careful consideration for benefit-risk assessment, especially for the SCIT form of administration and for those with moderate to severe asthma. Experience with SLIT is more limited in terms of allergens currently approved for administration, but it does offer the benefit of a safer form of AIT administration.

# Omalizumab

## Mechanism of Action

Omalizumab is the best studied of the new class of biologic medications for asthma. IgE is known to be important in the $T_H2$-related asthma response[40–46] and binds to high-affinity receptors on basophils, mast cells, and neutrophils,[40] leading to the release of inflammatory mediators, which are part of the allergic cascade that leads to asthma-related symptoms (Fig. 48.2).



Omalizumab
Decreases IgE related facilitation of antigen presentation
Decreases IgE production
Binds free IgE
Reduces eosinophils in blood, sputum, tissue
Decreases mediator release
Decreases high affinity receptor expression
Allergen
Dendritic cell
$T_H2$ cell
B-cell
IgE
FcεRI receptor
Neutrophil
Mast cell
Basophil
Eosinophil
TNFα
IL-4
IL-5
Histamine
cys-LT's
prostagandin
Degranulation/ release of mediators
Allergic response

**FIG. 48.2** Omalizumab binds to free IgE, inhibiting its ability to bind with the high affinity FcεRI receptor on mast cells, basophils, neutrophils, and eosinophils, therefore decreasing degranulation and release of mediators of allergic inflammation. *FcεRI,* High affinity IgE receptor; *IL,* interleukin; *LT,* leukotriene; *TGF,* transforming growth factor; *TNF,* tumor necrosis factor.[41]

Eosinophils also contain a high-affinity IgE receptor.[41] IgE also has the ability to facilitate antigen presentation to T cells, allowing small amounts of antigen to provoke a $T_H2$-related asthma response.[40] Omalizumab is a humanized, anti-IgE-specific form of IgG for the treatment of asthma.[41] It binds to circulating IgE, preventing it from binding with both high- and low-affinity receptors on effector cells, leading to a reduction in the release of allergic mediators.[42] Importantly, it does not cross-link bound IgE, which could amplify the allergic cascade and increase the risk of anaphylaxis.[43] IgE levels are decreased in the airway mucosa, as well as in the blood after 16 weeks of treatment, indicating good penetration to the affected tissues.[44] Reports have shown that treatment with omalizumab reduces cellular activation, leading to basophil and mast cell degranulation,[45] as well as modifying dendritic cell antigen presentation mechanisms.[46] In addition, there is early evidence that omalizumab may also downregulate bronchial smooth muscle proteins, indicating a possible role in disease-modifying remodeling.[47] There is evidence that omalizumab actually decreases IgE production over time, indicating that indefinite treatment may not be required.[48] One evaluation of shorter-term therapy showed that after 7 months of treatment, withdrawing omalizumab led to a recurrence of symptoms.[49] One study recommended a minimum duration of treatment of 12–16 weeks to fully assess treatment response.[50] Another study evaluated patients 3 years after the discontinuation of omalizumab therapy (which they had received for 6 years), and found that most patients continued to have reduced asthma symptoms at that time.[51]

# Pharmacology

## Pharmacodynamics

In vitro allergen-stimulated basophil histamine release is reduced by approximately 90% in treated subjects.[52] Serum-free IgE values are reduced within 1 hour of the first dose, and this is maintained between doses, and immediately after treatment discontinuation, IgE levels return to pretreatment levels without any evidence of rebound.[52]

## Pharmacokinetics

### Bioavailability.

After subcutaneous administration, average bioavailability is approximately 62%.[52] It is absorbed slowly and reaches peak serum concentrations after approximately 7–8 days. Pharmacokinetics are linear at doses greater than 0.5 mg/kg.[52]

### Distribution.

Omalizumab forms complexes of limited size with IgE, without evidence of precipitation of these complexes.[52] The apparent volume of distribution following subcutaneous administration is approximately 78 ± 32 mL/kg.[52]

### Elimination.

Clearance occurs via IgG elimination processes as well as via complex formation with IgE.[52] Liver elimination occurs via degradation in the reticuloendothelial system and endothelial cells, and intact IgG is excreted in bile.[52] Serum elimination half-life averages 26 days, clearance averages 2.4 ± 1.1 mL/kg per day, and the doubling of body weight doubles clearance.[52] There is no evidence for a need for dose adjustment, due to factors such as age (above 6 years), race/ethnicity, gender, and there is no available data at this time regarding dosing in renal or hepatic impairment.[52]

## Mode of Administration

Omalizumab is administered via subcutaneous administration every 2–4 weeks, depending on the weight and IgE level of the patient.[42] Clinicians should not administer more than 150 mg per injection site, and be prepared and equipped to identify and treat anaphylaxis should this occur.[6] Observation for 2 hours postinjection for the first three injections and 30 minutes postinjection thereafter has been recommended.[53,54]

## Dosing Strategies

Dosing tables exist, based on a combination of total IgE and weight, to guide omalizumab dosing, and reducing doses below those recommended has been shown to increase free IgE and thus could cause a reduction in asthma control.[49] European guidelines specify a maximum dose of 600 mg every 2 weeks and do not support dosing in IgE levels above 1500 IU/mL.[52] US guidelines specify a maximum dose of 300 mg for every 4-week dosing or 375 mg for every 2-week dosing, and do not support dosing in IgE levels above 700 IU/mL if administered every 4 weeks, 1300 IU/mL if administered every 2 weeks.[55] Country-specific dosing tables are available and should be consulted to determine patient-specific dosing. Unfortunately, a significant proportion of asthmatic children and adolescents that may benefit from omalizumab therapy may not qualify due to elevated IgE levels,[56] and though current dosing tables are close to optimal, it may be possible to treat patients with higher baseline IgE levels than currently recommended.[57] This area will need to be continually studied in order to fully optimize treatment for all asthmatic children and adolescents.

# Clinical Studies

## Adult Studies

Omalizumab has been shown to be effective in the adult population across a wide range of clinical outcomes, including asthma exacerbations,[58–64] ED (emergency department) visits/hospitalizations,[63,65,66] exhaled nitric oxide,[58] asthma control test (ACT),[60] quality-of-life scores,[58,61,64,67] unscheduled physicians visits,[58] decreasing ICS requirements,[67] and airway wall thickness.[58] Omalizumab has also been shown to be effective in nonatopic asthmatic adults,[68] though not all data supports its use in this population.[69]

## Child Studies

The studies described previously were largely conducted on adolescents and adults 12 years of age or older. The remainder of the literature in children focuses on the 6–18-year-old population. Omalizumab has also been shown to improve exacerbation rates,[56,70–74] decrease inhaled and oral corticosteroid doses,[70,72,73,75] and improve asthma-related quality-of-life scores,[75–77] ACT,[75] asthma control,[72] and lung function.[70] Omalizumab has also been found to be a potential alternative to treatment in patients who have poor adherence to ICSs.[78] In addition, omalizumab has been shown to improve interferon alpha (IFN-$\alpha$) responses to rhinoviral infection in children.[71]

# Safety

Early concerns with the use of omalizumab included concerns of anaphylaxis, serum sickness, and even risk for malignancy. Omalizumab has a mostly good safety and tolerability profile[79] and no significant development of omalizumab specific antibodies,[80] although urticaria is a potential side effect.[81] One meta-analysis of 2749 patients receiving omalizumab therapy showed similar rates of minor adverse effects in treatment and placebo groups and a slightly lower incidence and profile of serious adverse effects in the omalizumab groups.[82] The safety and tolerability of omalizumab in children remains stable over longer time frames (52 weeks) as well.[81] Anaphylaxis does remain a risk with omalizumab injection (see the notes on monitoring given previously), however, and clinicians should be aware that it may be characterized by delayed onset (>2 hours after dose) and protracted progression of symptoms[83]; patients should be trained in the recognition of anaphylaxis and use of epinephrine autoinjector use, and be sent home with an epinephrine autoinjector.[54] Pain and swelling at the injection site occurs in 5%–20% of patients.[6] The EXCELS study evaluated 7857 patients, of whom 5007 were treated with omalizumab, and found that omalizumab was not associated with any increased risk of malignancy.[84] However, there is evidence that omalizumab may increase the risk of cardiovascular and cerebrovascular events.[84a]

## Clinical Application—Current and Future Considerations

### Age

Currently omalizumab is approved in the US and Europe in children greater than 6 years of age, adolescents, and adults. Further study is needed to determine safety and efficacy in children younger than 6 years of age.

### Biomarkers

Omalizumab has effects on several biomarkers. It is known to decrease serum free IgE,[44,85] and it also reduces sputum and tissue eosinophils and airway lymphocytes[44] and reduces basophil numbers.[86]

### Target Response Expected

There is evidence that patients with high baseline levels of fractional exhaled nitric oxide (FeNO), eosinophils, and serum periostin have the greatest improvement in exacerbation frequency with omalizumab compared with placebo.[62] In addition, the response to inhaled allergens in asthma is diminished by omalizumab, and this decrease is paralleled by a reduction in eosinophils and IgE bearing cells.[87] However, it is important to recognize that monitoring IgE alone does not predict clinical response in omalizumab treated patients.[85]

### Other Diseases

Omalizumab has been studied in various other diseases as well, has been shown to be effective in allergic rhinitis and allergic bronchopulmonary dysplasia (ABPA), and has been found equivocal in nasal polyposis.[69] In addition, it has been utilized successfully for the treatment of chronic urticaria.[88]

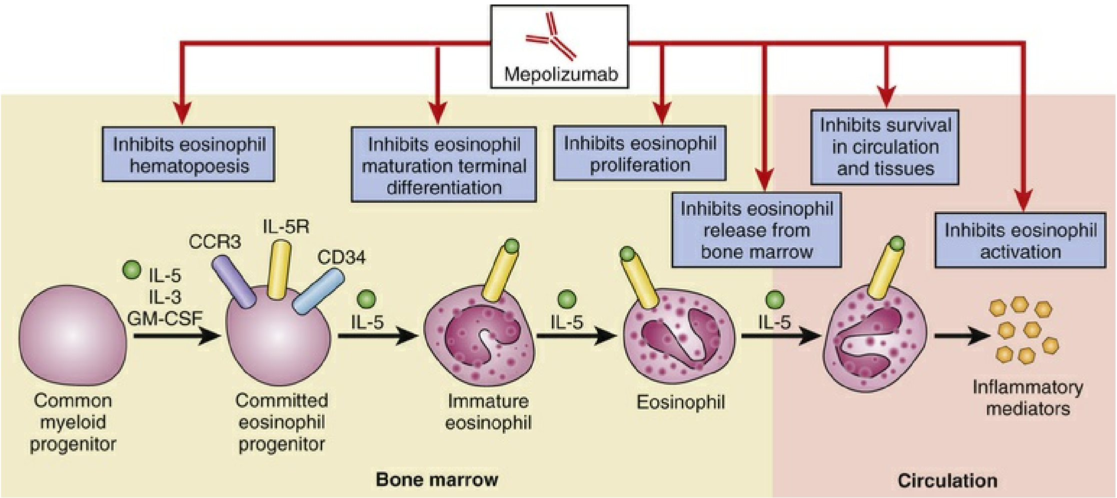
### Cost Effectiveness

Omalizumab currently remains a high-cost therapy for asthma treatment. Studies have shown it to be cost effective with regard to decreasing exacerbations and improving health-related quality of life when used in severe asthmatic adults.[89,90] The selection of patients to receive omalizumab therapy should focus on those children who have severe allergic asthma in order to maximize cost efficiency.

# Mepolizumab

## Mechanism of Action and Target Effects

Mepolizumab is a humanized murine monoclonal IgG1κ antibody directed against interleukin-5 (IL-5).[91–93] The IL-5 receptor is composed of the IL-5Rα chain, which binds IL-5, and the common β chain (βc), which mediates the signal transduction (Fig. 48.3).[94–97] Mepolizumab binds to IL-5, preventing its interaction with the IL-5 receptor and subsequent signaling.[92]



Mepolizumab
Inhibits eosinophil hematopoesis
Inhibits eosinophil maturation terminal differentiation
Inhibits eosinophil proliferation
Inhibits eosinophil release from bone marrow
Inhibits survival in circulation and tissues
Inhibits eosinophil activation
IL-5R
CCR3
CD34
IL-5
IL-3
GM-CSF
IL-5
IL-5
IL-5
Common myeloid progenitor
Committed eosinophil progenitor
Immature eosinophil
Eosinophil
Inflammatory mediators
Bone marrow
Circulation

**FIG. 48.3** The impact of mepolizumab on IL-5 in eosinophil development and function. Mepolizumab binds to IL-5 inhibiting its ability to bind with the IL-5 receptor. By blocking IL-5, mepolizumab inhibits eosinophil hematopoiesis, maturation, differentiation, and proliferation in the bone marrow as well as eosinophil migration into circulation. In the tissue and circulation, mepolizumab prevents IL-5-mediated eosinophil survival and activation. *CCR3*, C-C chemokine receptor type 3; *GM-CSF*, granulocyte macrophage colony-stimulating factor; *IL*, interleukin.

IL-5 is predominantly synthesized by CD4+ $T_H2$ lymphocytes but also is produced in smaller amounts by mast cells, eosinophils, basophils, NK T cells, group 2 innate lymphoid cells, and CD34+ progenitor cells.[91,94–97] The presence of the IL-5 receptor, along with CD34 and CCR3, designate stem cells for eosinophil development.[98,99] IL-5 is responsible for eosinophil hematopoiesis, proliferation, maturation, and terminal differentiation in the bone marrow and mobilization of the eosinophils from the bone marrow into circulation.[91,93–97] IL-5 enhances chemotaxis and adhesion of eosinophils to the vascular wall in the circulation and increases eosinophil activation, degranulation, and cytotoxicity in tissues.[91,95,97] The presence of locally generated IL-5 promotes the survival of eosinophils in tissues, and in vitro studies have demonstrated that the absence of IL-5 results in spontaneous cellular apoptosis.[91,93,94] Patients with asthma have increased IL-5 in their bronchoalveolar lavage fluid and bronchial biopsies at baseline, with an upregulation in bronchial mucosa IL-5 mRNA and serum IL-5 after allergen provocation.[94,97,100]

The inhibitory effect of mepolizumab on eosinophils through suppression of IL-5 has been well demonstrated. In both asthmatics as well as patients with eosinophilic syndromes, mepolizumab reduced, but did not completely deplete, peripheral blood,[100–106] airway/sputum,[100,103–105,107] and bone marrow[98,100,107] eosinophil counts, with the greatest effect being reduction of blood eosinophil counts. Mepolizumab also decreased eosinophil precursors, including eosinophil myelocytes and metamyelocytes, in the bone marrow, inducing partial maturational arrest of the eosinophil lineage.[98] In patients with eosinophilic syndromes, mepolizumab did increase serum IL-5 levels, IL-5R$\alpha$ expression, and percentage of CD4+ and CD8+ T cells, producing intracellular IL-5.[102]

# Pharmacology

## Pharmacodynamics

Mepolizumab has been studied in intravenous and subcutaneous forms. The route of administration has been found not to affect the exposure-response relationship.[108] Utilizing an indirect pharmacological response model, mepolizumab demonstrated a maximal decrease in peripheral eosinophil counts of 85% from baseline, with a half-maximal inhibitory concentration ($IC_{50}$) of 0.045 μg/mL.[92] A nonlinear inhibition $I_{max}$ model based on blood eosinophil levels after 12 weeks of therapy identified subcutaneous mepolizumab doses of 11 mg and 99 mg, provided 50% and 90% of maximal blood eosinophil inhibition, respectively.[108] Studies using intravenous (IV) mepolizumab have demonstrated a dose-dependent decrease in blood[105,108] and sputum[105] eosinophil levels. In a study of adult patients administered mepolizumab every 4 weeks for 8 weeks, there was a pronounced reduction as early as day 3 (first postdose measurement), with a return to baseline from day 70 (2 weeks postlast dose) to day 140 (last day of follow-up).[108] A sustained decrease in blood eosinophilia has been observed even 3 months after the final infusion in 76% of patients with eosinophilic syndromes.[102] An observational study demonstrated that following discontinuation of mepolizumab, there were significant increases in serum eosinophil counts, with a return to baseline over 6 months.[109] Sputum eosinophil counts increased over 3 months after discontinuation of mepolizumab, but not thereafter.[109]

Mepolizumab induces an increase in blood IL-5 levels, likely secondary to circulating IL-5/mepolizumab complexes precipitating with protein A/G.[102,108] In the aforementioned study of adults treated with mepolizumab, IL-5 increased until day 28 of treatment and remained constant up to the last day of follow-up, at day 140.[108] Upon discontinuation of mepolizumab, however, patients did not have a rebound phenomenon in their eosinophil counts secondary to this increased IL-5 during treatment.[109] No relationship was found between levels of serum total IL-5 and mepolizumab plasma concentrations.[108] Patient response to mepolizumab is not related to baseline plasma IL-5 levels.[102]

### Pharmacokinetics

Pharmacokinetics for mepolizumab are dose proportional and time-independent.[92] Mepolizumab has an absolute bioavailability of 64%–75% following subcutaneous injection[92,108] and 81% following intramuscular injection.[92] The median time to maximal concentration ($t_{max}$) is 6–8 days postdosing, with subcutaneous administration compared with 0.5 hours with intravenous administration.[108] The steady-state volume of distribution ranges from 49 to 93 mL/kg.[92] The exact route of elimination for mepolizumab is unknown but is believed to be similar to that of other IgG1 antibodies.[92] Mepolizumab is eliminated slowly with a terminal half-life of 20 days,[92] with another study showing a range of 22–28 days for subcutaneous and IV administration, respectively.[108] Mepolizumab plasma clearance ranges from 0.064 to 0.163 mL/h/kg.[92] There is no available data regarding dosing in renal or hepatic impairment.[92]

## Mode of Administration and Dosing

Early studies of mepolizumab trialed multiple doses with a progression from an intravenous to a subcutaneous formulation.[103–107,110] Mepolizumab is currently administered as a 100 mg subcutaneous injection every 4 weeks.[111]

## Biomarkers to Direct Use

Initial studies of mepolizumab that recruited patients on the basis of asthma severity but not markers of eosinophilia showed a reduction in sputum and blood eosinophilia but failed to show an improvement in any clinical endpoints compared with placebo, including exacerbations, symptom scores, $FEV_1$, quality of life, or $\beta_2$-agonist use.[107] Subsequent studies explored mepolizumab use in patients with eosinophilic asthma, defined as either a sputum eosinophil percentage greater than 3%,[103–105] FeNO of 50 ppb or greater,[105] or a peripheral eosinophil count of 300 cells/μL or greater in the previous year or at least 150 cells/μL at screening.[105,106,110] Directing the therapy toward patients with this eosinophilic phenotype demonstrated an improvement in clinical outcomes, outlined later. In particular, exploratory modeling of baseline characteristics indicated that those patients with a higher eosinophil count, including greater than 300 cells/μL, and a higher number of exacerbations in the previous year, were most predictive in achieving a reduction in asthma exacerbations with mepolizumab.[105]

## Clinical Studies

Mepolizumab was initially studied in adults, with only recent studies enrolling adolescents as young as 12 years old, thereby limiting insight into pediatric use.[112] In patients with eosinophilic asthma with recurrent severe exacerbations in the past 12 months despite the use of high-dose ICSs, with or without a long-acting beta-agonist or maintenance oral corticosteroids, mepolizumab reduced the number of severe exacerbations,[103–106,110] reduced exacerbations requiring emergency room visits or hospital admission,[105,106] and delayed the time to first exacerbation,[105] compared with placebo. In patients with severe eosinophilic asthma with refractory symptoms requiring daily oral corticosteroids, mepolizumab allowed a reduction in their oral corticosteroid dose while improving asthma control compared to placebo.[104,110] Initial studies with mepolizumab in eosinophilic asthmatics failed to show an improvement in $FEV_1$,[103,105] asthma control, or symptom scores,[103,105] with subsequent studies demonstrating an improvement in these parameters[104,106,110] compared with placebo. Mixed results have been observed on the effect of mepolizumab on quality of life, with some studies showing improvement[103] and others showing no change.[105] Following discontinuation of therapy, there was a significant increase in severe asthma exacerbations over a 12-month observation period in those previously treated with mepolizumab, with the exacerbation rate at the end of the 12-month period being similar between subjects whose mepolizumab was discontinued and subjects originally treated with placebo.[109]

### Safety

Overall, mepolizumab has a favorable safety profile, with most adverse events being reported as mild or moderate in intensity and no fatalities reported.[108] The most frequently reported adverse event was injection site reaction,[108] with other common adverse events, including upper respiratory infections, asthma, headaches, rhinitis, bronchitis, sinusitis, viral infection, injury, back pain, nausea, and pharyngitis.[107] Given mepolizumab's impact on eosinophils, it is recommended that patients with preexisting helminth infections be treated before the initiation of therapy.[111] In clinical trials, two serious adverse reactions of herpes zoster occurred in patients on mepolizumab, prompting a consideration for varicella vaccination if medically appropriate before starting therapy.[111]

**Clinical Application.** Mepolizumab is currently approved for the treatment of eosinophilic asthma in the United States for patients 12 years of age and older. The experience in adolescents is admittedly with a comparatively smaller number of adolescents than adults. Based on less experience, it could be a consideration for patients who do not qualify for omalizumab therapy or an alternative to omalizumab in the distinctly eosinophilic phenotype.

## Other Biologics

### Reslizumab

Reslizumab is a monoclonal antibody directed against IL-5, differing from mepolizumab by being a humanized rat IgG4κ antibody.[113,114] Given its target of IL-5, reslizumab also decreases sputum[113] and peripheral blood eosinophils.[113,114] Following discontinuation of therapy, patients on reslizumab had a return of their eosinophil counts to baseline by 90 days.[113] Similar to mepolizumab, reslizumab has been studied in eosinophilic asthma, defined as a sputum eosinophil count greater than 3%[113] or a peripheral serum eosinophil count of 400 cells/μL or greater,[114] which is higher serum eosinophil cutoff than that used for mepolizumab.[112] When used in patients with poorly controlled eosinophilic asthma despite the use of at least medium-dose ICSs and another controller medication, reslizumab reduced asthma exacerbations, increased time to first exacerbation, and improved $FEV_1$, quality-of-life scores, and asthma control scores,[114] compared with placebo.

## Benralizumab

Benralizumab is a monoclonal afucoslylated IgG1κ antibody directed against the IL-5Rα chain.[115,116] Afucosylation of IgG1 increases its affinity for FcγRIIIa, which is expressed on natural killer cells, macrophages, and neutrophils.[116] This results in enhanced antibody-dependent cell-mediated cytotoxicity of eosinophils through the interaction of benralizumab and with FcγRIIIa.[116] Benralizumab reduces peripheral blood eosinophil counts in a dose-dependent fashion, with a marked reduction in peripheral blood,[115,117,118] sputum,[117] airway mucosa,[117] and bone marrow[117] eosinophil counts. In a phase 2b dose ranging study of adults with uncontrolled asthma with recurrent exacerbations despite the use of medium- or high-dose ICSs and long-acting beta-agonists, benralizumab reduced exacerbation rates in those patients with a peripheral blood eosinophil count of at least 300 cells/μL.[119] Those patients with eosinophilic asthma had improvement in both $FEV_1$ and asthma control scores.[119] In adult asthmatic patients with a prior exacerbation in the 12 months presenting to the ED with an acute asthma exacerbation, a single administration of benralizumab reduced asthma exacerbation rates and exacerbations, resulting in hospitalization over the following 12 weeks, compared with placebo.[118] This may present a unique application of this therapy in managing acute asthma and calls for further studies in children and adults in relation to dose and timing.

## Dupilumab

Dupilumab is a monoclonal antibody to the interleukin-4 receptor α subunit, which should inhibit both IL-4 and IL-13 downstream signaling.[120] Dupilumab has been shown to be effective in moderate to severe adult asthmatics who were already being treated with ICS and LABA medications, with fewer exacerbations upon withdrawal of these medications in dupilumab treated patients,[120] and phase II trial in adults showed that it was effective in improving lung function and reducing exacerbations.[121] Further study is needed to determine the efficacy of this drug in children.

# Conclusion

As indicated in this review, there is good evidence that AIT has the capacity to induce at least a temporary remission in asthma symptoms after 3 years of administration, but alteration on progression of disease, especially in relation to irreversible loss of pulmonary function associated with disease progression, has not been evaluated. Similarly, the new immunomodulators, including omalizumab, have shown promise in reducing asthma exacerbations with variable effects on other features of the disease, such as symptoms and pulmonary function. However, studies to date have not shown that these medications can alter the course of the disease and lead to remission after discontinuation. Aside from omalizumab and mepolizumab, the effects of the other new agents in adolescents have not been reported. In addition, omalizumab and mepolizumab are not approved for use in children less than 12 years of age in the United States. As experience is obtained in adults and adolescents, and safety profiles established, there will be a gradual progression of studies in younger children. Hopefully, one or more of these agents will be successful in altering the course of the disease, as it often presents in early childhood. It will be necessary to define the effect of the various immunomodulators, and the profile of the child most likely to benefit, to establish the cost effectiveness of this line of treatment. Future studies may determine that combination immunomodulators may be needed to obtain the full effect on altering the early onset and progression of asthma.

# Genetics and Pathophysiology of Cystic Fibrosis

*Garry R. Cutting MD, John Engelhardt PhD, Pamela Leslie Zeitlin MD, PhD*

The genetic basis of cystic fibrosis (CF) has been recognized by the medical community since the 1940s.[1] A genetic etiology and autosomal-recessive inheritance was suggested by the recurrence of CF in siblings and the absence of the illness in parents. Genetic linkage analysis confirmed that a single locus was responsible for classic CF.[2,3] In 1989, technical breakthroughs allowing identification of disease-causing genes on the basis of position rather than function enabled Tsui and colleagues to clone the gene responsible for this disorder.[4] The identified gene was aptly named the cystic fibrosis transmembrane conductance regulator *(CFTR)*.[5] During the past three decades, our understanding of the molecular basis of CF has exploded. We now recognize that deleterious variants in *CFTR* give rise to a range of phenotypes, extending from classic CF to single-organ pathology. The successful use of therapies directed at the complications of CF has raised the question as to the potential efficacy in disease phenotypes that mimic CF, including idiopathic bronchiectasis,[6,7] chronic *Pseudomonas aeruginosa* airways colonization in tracheostomy patients,[8] or chronic obstructive pulmonary disease.[9] The assumption that all carriers of a single disease-causing variant in *CFTR* are asymptomatic also has been questioned. The consequences of many variants on the function of the encoded protein have been determined, allowing correlation of altered function of *CFTR* with CF pathophysiology.[10] Two variant-specific *CFTR* modulator therapies are approved by the Food and Drug Administration (FDA) in the United States.[11,12] Additional investigational molecules capable of repairing several different classes of *CFTR* variants are in clinical trials in North America, Europe, and Israel, potentially increasing the number of patients eligible for drugs directed at the primary cause of CF.

# *CFTR* Gene

## Structure

The *CFTR* gene resides on the long arm of human chromosome 7 and encompasses approximately 189,000 base pairs of DNA.[13] The coding portion of the gene is divided into 27 exons that are transcribed into a messenger RNA (mRNA) of approximately 6500 base pairs.[5] The exon and intron structure of the *CFTR* gene is well conserved among mammals and evolutionarily distant species such as amphibians (Xenopus) and fish (killifish and dogfish).[14]

Transcription of *CFTR* is initiated 80 base pairs upstream from the start site of translation.[15,16] The *CFTR* gene demonstrates exquisite temporal and spatial differences in expression. For example, specific cell types within the human lung express high levels of *CFTR*, while surface epithelial cells have a very low level of *CFTR* expression.[17] *CFTR* expression is also regulated during organ development.[18,19] Despite considerable evidence that the expression of *CFTR* is highly selective, the precise elements that regulate *CFTR* expression have not been identified. Sequences immediately upstream of the transcriptional start site of *CFTR* generate low-level expression in most tissues. This pattern of expression is consistent with the presence of basal promoter elements.[20,21] A cyclic adenosine monophosphate (cAMP) response element has been identified within this region of *CFTR*, but this element does not appear to account for the spatial and temporal expression patterns.[22] Assays that search for binding of protein to

DNA have identified several regions elsewhere in the *CFTR* gene that may be involved in transcriptional regulation.[23] Strain-specific differences in *CFTR* expression in mice have been mapped to sequences about 700 base pairs upstream of the *CFTR* gene, indicating the existence of regulatory elements in this region.[24] Epigenetic mechanisms such as methylation do not appear to play a major role in regulating *CFTR* expression.[25,26] However, there is growing evidence that microRNAs (miRNA) modulate the level of *CFTR* mRNA transcripts.[27,28] Thus, despite extensive efforts to locate transcriptional elements, the molecular mechanisms regulating *CFTR* expression are not completely understood.

## Splicing

Variations in *CFTR* splicing patterns have been identified by the reverse transcription-polymerase chain reaction technique.[29,30] There are relatively few alternatively spliced transcripts that create functional isoforms of *CFTR*.[31] RNA transcripts resulting from alternative splicing of exon 5 *CFTR* create a functional form of *CFTR* in the rabbit heart but have not been identified in other species or organs. Transcripts missing a portion of exons 13 and 14a encode a functional isoform of *CFTR* expressed in mouse and human kidney.[32] Neither the heart nor the kidney appears to be primarily involved in CF pathophysiology; thus the role of these alternatively spliced forms of *CFTR* is unclear.

In contrast to alternative splicing, many aberrantly spliced versions of *CFTR* have been identified. Aberrantly spliced *CFTR* RNA transcripts do not produce functional *CFTR*. Aberrant splicing occurs as a result of variation in intronic or exonic sequences required for normal splicing of *CFTR*. The aberrant splicing of exon 10 (legacy exon 9) is a notable example.[33,34] Variation in the length of the polythymidine tract, an element in the 3′ splice site of intron 9, is correlated with the amount of properly spliced *CFTR* mRNA.[35] Longer versions of this tract called 9T and 7T are common in the population and are associated with high levels of normally spliced *CFTR* mRNA. A shorter version of this tract called 5T is associated with a substantial reduction in full-length *CFTR* RNA.[36] While abbreviated polythymidine tracts in 3′ splice sites do not usually cause mis-splicing of the subsequent exon, it appears that a special situation occurs in the *CFTR* gene. Sequence surrounding exon 9, including unusual variation in splice sites surrounding exon 9 and splice-silencing sequences in intron 9, appear to make exon 9 vulnerable to mis-splicing.[37–39] Thus alterations in secondary splicing signals of this exon such as the polythymidine tract have an exaggerated effect on splicing. The splicing efficiency of *CFTR* genes bearing 5T also varies by tissue. The vas deferens splices *CFTR* genes bearing the 5T variant less efficiently than respiratory epithelia, which explains the existence of congenital bilateral absence of the vas deferens (CBAVD) without other symptoms.[40,41]

Individuals carrying the 5T variant in their other *CFTR* gene manifest a variety of phenotypes, ranging from healthy to nonclassic CF (discussed later). The latter phenomenon is due to the variable effect that 5T has on the splicing of *CFTR* exon 9. This splicing variability is caused by variation in the number of TG dinucleotides adjacent to the polythymidine tract.[42] The role of the TG tract in splicing of 5T alleles is controversial. It may serve as a site for binding of a splicing repressor, or the RNA may form a secondary structure such as a hairpin that affects gene expression.[43,44] Either way, there is a robust correlation between the length of the TG tract and the phenotypes associated with a 5T variant.[45]

Many other *CFTR* transcripts derived from aberrant splicing of exons 9 through 12 have been reported, yet none appear to be correlated with phenotype.[30,46–49] Another example of aberrant *CFTR* splicing involves exons 23 and 24, resulting in a prematurely truncated *CFTR* protein that is nonfunctional.[50] The many variants that affect *CFTR* splicing and result in disease are summarized in the following section.

## DNA Variants

More than 2000 variants in the *CFTR* gene associated with disease have been reported to the Cystic Fibrosis Genetic Analysis Consortium (http://www.genet.sickkids.on.ca/cftr/). The Consortium website has implemented variant nomenclature according to Human Genome and Variome Society (HGVS) guidelines. Variants are now provided in legacy and HGVS format (http://www.genet.sickkids.on.ca/cftr/). Legacy names are used in this chapter, and the HGVS nomenclature is provided with the first mention of a variant. The vast majority of *CFTR* variants reported to be associated with disease involve only one or a few nucleotides. Nearly 50% of variants change an amino acid, while variants that affect splicing or introduce a nonsense codon account for approximately 25%. Deletion and insertion variants that alter the reading frame and usually result in the introduction of a premature termination codon account for about 20%. Deletions and insertions involving multiples of three nucleotides are much less common (2%). The latter variants do not shift the reading frame, so a protein missing one or more amino acids is usually produced (e.g., *CFTR* with the F508del [HGVS p.Phe508del] variant). Most of the remaining disease-associated variants (3%) involve the deletion of larger regions of DNA involving hundreds to thousands of base pairs. Finally, a few variants (1%) have been purported to occur in sequences thought to be involved in transcriptional regulation of the *CFTR* gene, although a convincing case has been made in only a few instances.[51] In addition to the disease-associated variants, almost 270 variants in *CFTR* have not been associated with disease. There are some variants in *CFTR* (e.g., *M470V* HGVS p.Met470Val) that may affect phenotype.[42,52] Variants that are “silent” (that do not change an encoded amino acid or known splicing signal) are not predicted to alter *CFTR* function. However, the elucidation of intronic and exonic signals that enhance or repress exon splicing raises the possibility that some “silent” changes may affect *CFTR* splicing.[53–55]

The distribution of disease-associated variants in the *CFTR* gene among human populations has been extensively reviewed.[56,57] One variant, a deletion of three nucleotides that leads to loss of a single phenylalanine residue at codon 508 (F508del), accounts for approximately 70% of CF alleles in Northern European Caucasians. The frequency of the F508del variant varies on the European continent from less than 50% of CF alleles in Southern Europe to as high as 88% of CF alleles in Denmark. The F508del variant is quite rare in native Africans and native Asians. However, the F508del variant is found in racially admixed populations. For example, 30%

of the *CFTR* genes in American CF patients of African descent have the F508del variant.[58] On the other hand, the second most common variant in African Americans with CF (3120 + 1G>A; HGVS c.2988 + 1G>A) appears to be a common CF allele in native Africans.[59,60] Deleterious CF alleles also have been found in CF patients of Asian ancestry.[61,62] These variants have not been observed in Caucasians or native African populations. Thus rare deleterious variants in the *CFTR* gene occur in all human populations. However, it is the frequency of the F508del variant in Europeans that accounts for the high incidence of CF in Caucasians.

In addition to F508del, only about 25 other variants occur, with a frequency of 0.1% or greater in the Caucasian CF population.[58,63] Other variants are seen with some frequency in African Americans.[59] Finally, some ethnic groups have one or more variants that reach a frequency of ≥1% that are rare in the general population. The higher frequency of the latter variants is probably the consequence of a founder effect.[64] The remainder of the reported variants (~1000) has been reported in only a small number of individuals. Screening for the F508del variant and 22 variants that have a frequency of greater than 0.1% detects about 85% of variants in Caucasian CF patients.[65] Variant screens involving 50–100 CF variants produce a minimal increase in detection rate in the general CF population (1%–3%). Because there are so many rare variants, in order to achieve a detection rate for classic CF over 95%, screening of the entire coding region of the *CFTR* gene is required.[66,67]

# *CFTR* Protein

## Characteristics

The *CFTR* protein is composed of a linear stretch of 1480 amino acids that form an integral membrane glycoprotein. A comparison of the nucleotide sequence across available databases places this protein as a member of the ABC transporter superfamily. The topology of the protein contains the common features of twofold symmetry with six transmembrane domains and an intracellular nucleotide-binding fold. The *CFTR* is unique in the presence of a central intracellular R domain enriched in phosphorylation sites used by the protein kinases A and C. Although most members of the superfamily are transporters (e.g., the multidrug resistance transporter (MDR) transports chemotherapy agents), the *CFTR* is a cAMP-regulated chloride and bicarbonate channel that must function for the outwardly rectifying chloride channel (ORCC) to transport chloride. Functional *CFTR* also downregulates the epithelial sodium channel (ENaC) in those cells in which both reside. More controversial functions have been reported, including transport of nucleotides and fatty acids.

## Biogenesis

The *CFTR* polypeptide is translated from the mRNA in the endoplasmic reticulum (ER) as a linear chain of amino acids with hydrophilic (water-soluble) and hydrophobic (lipid-soluble) domains. The nascent polypeptide is assisted by interactions with chaperone proteins within and outside the ER, to assume a tertiary or folded structure that buries the membrane-spanning domains in the ER membrane. The process is relatively slow, taking approximately 10–15 minutes to complete, and is followed by two different fates. Depending on the cell type making the *CFTR*, the wild-type (WT) chain could be ubiquitinated and sent to the proteasome for degradation,[68] or it could continue along the trafficking pathway to the Golgi apparatus. Chloride transport through the *CFTR* can be detected in the ER using patch-clamping techniques, but it is not known whether the immature functional channel is the one protected from proteasomal degradation. The successful *CFTR* is packaged into vesicles for transport.[69] Adequate anion channel transport through cell surface *CFTR* depends not only on the characteristics of the channel pore or degree of phosphorylation and ATP hydrolysis but also on numbers of *CFTR* proteins and residence time at the surface. *CFTR* is actively recycled from the plasma membrane, and some mutants are much less stable than WT-*CFTR*.[70]

## Function

The three-dimensional topology of *CFTR* is under investigation. The two nucleotide binding domains (NBDs) and the R domain probably interact such that phosphorylation of the R domain is required for chloride channel opening and probably affects the affinity of the NBDs for adenosine triphosphate (ATP).[71] ATP hydrolysis at NBD1 is associated with opening the channel, but hydrolysis at NBD2 is associated with closure. The chloride pore is formed by transmembrane domains, and the single-channel conductance is low, at 6–10 picosiemens. The current-voltage relationship is linear, meaning that it is just as easy for chloride to leave as to enter the cell, depending on the direction of the voltage applied across the membrane. This bidirectionality is possible because ATP is the ligand that is hydrolyzed to gate the channel.

The most common variant in *CFTR,* the F508 deletion of the code for phenylalanine at position 508, has two consequences. First, the channel has a low open time for chloride—about 10% of normal.[72,73] Second, the newly translated *CFTR* is unstable in the ER, leading to premature proteolysis and a reduced half-life in the cell. The variant appears to affect intermolecular interactions within *CFTR* rather than NBD1 folding.[74,75]

## Cellular Distribution and Function

### Developmental Expression and Function

*CFTR* mRNA is detectable in many fetal tissues in the first trimester. Data have been collected for fetal lung, intestine, pancreas, and kidney from humans, rats, rabbits, and mice. During early mammalian embryonic tissue development, *CFTR* may be more important as a regulator of other ion channels rather than as a pathway for chloride transport.[76] *CFTR* protein becomes detectable in the second trimester, still quite early in development. *CFTR* expression declines in postnatal lung, and this decline begins even earlier in the rat, during the last trimester. There is a bronchial centrifugal expression gradient and a developmental shift from nonpolar localization to apical localization, with a timing that matches that of *CFTR* regulation of the ENaC. In other words, since ENaC function is required to resorb fetal lung fluid at birth as an adaptation to air-breathing, *CFTR* expression, a downregulator of ENaC function, declines and ENaC expression increases.

### Postnatal Expression and Function

Regulated airway fluid and ion composition become more important for the air-breathing mammal than they were during lung development. CF lungs are morphologically normal at birth, in part because there are sufficient alternative chloride transport pathways in fetal lung to support tissue expansion and differentiation.[76] After birth, airway mucociliary clearance is affected by the depth and characteristics of the periciliary fluid layer, which in turn is dependent on ENaC function.[77–79] Over time, the human infant with pancreatic-insufficient CF is increasingly vulnerable to infection and inflammation in the airways, which lead to the classic lung phenotype of airways obstruction.

## Tissue Distribution

Absent or reduced function of *CFTR* can be measured quantitatively in the sweat duct, where the reabsorptive coil is designed to conserve chloride, sodium, and water to protect the mammal from dehydration. The diagnostic sweat test takes advantage of the cholinergic pathway for generation of sweat by the sweat gland coil. *CFTR* is only responsible for at most 1% of sweat generation but is required for chloride reabsorption in the duct, thus leading to elevated sweat chloride concentrations.

*CFTR* plays a vital role in several other organs, tissues where epithelial proteins are secreted along with electrolytes. The most important organs are the airways, bile ducts, pancreatic ducts, and vas deferens. Interestingly, although *CFTR* is highly expressed in the kidney, its absence is not detrimental. The simplified scheme in which *CFTR* plays an electrophysiologic role to control the ion and water content of luminal secretions is insufficient to explain the nature of CF lung disease. In CF lungs, additional abnormalities of fluid are associated with chronic inflammation and infection.

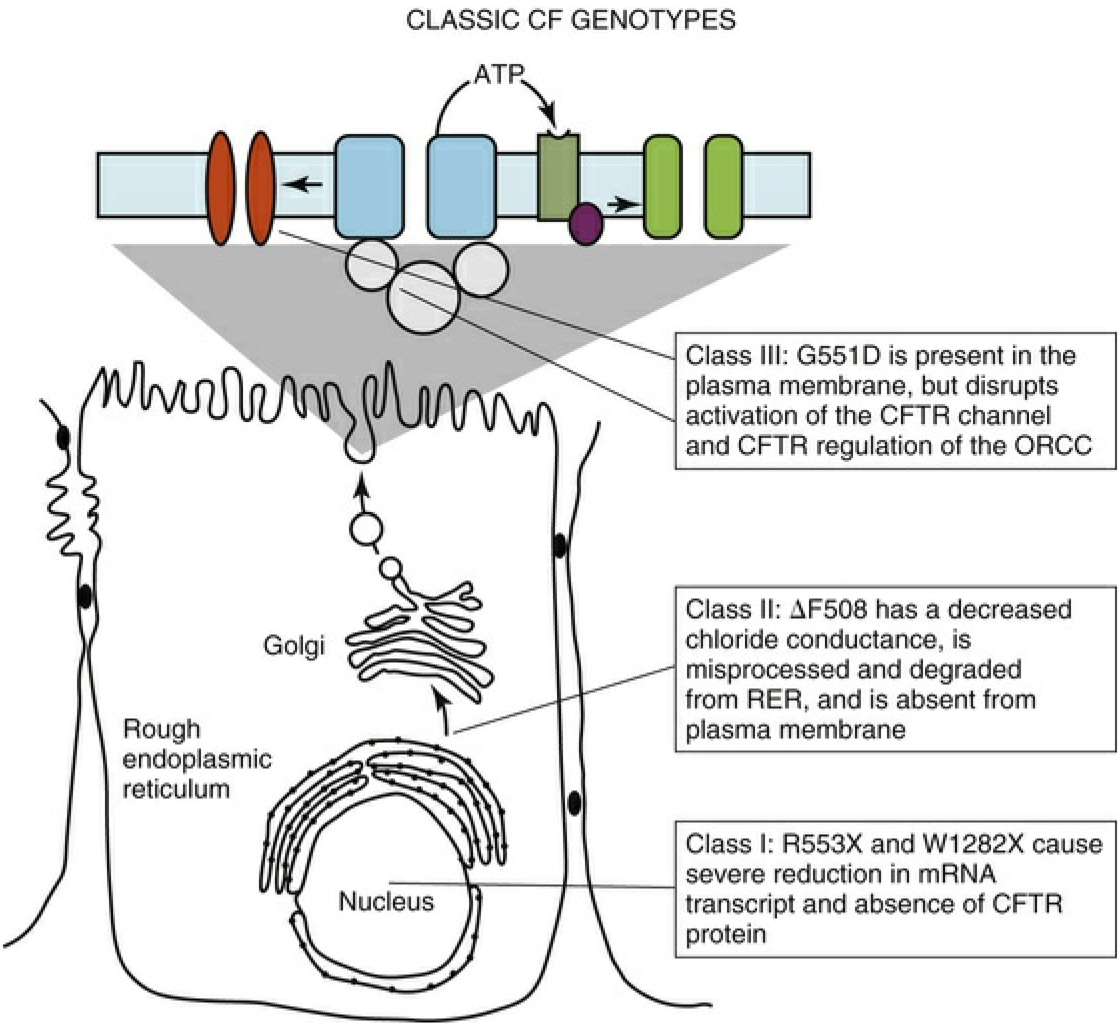
# Genotype-Phenotype Correlations

## Molecular Consequences of Variants

The implementation of newborn carrier screening for CF and the development of *CFTR* targeted therapies has brought renewed interest in the clinical and functional consequences of variants in *CFTR*. To increase the sensitivity and specificity of genetic testing for CF, a project entitled the Clinical and Functional Translation of *CFTR* or *CFTR*2 was undertaken. In its first phase, *CFTR*2 coordinated the collection of clinical data on almost 40,000 individuals with CF from 25 countries. These individuals carried 1,036 unique *CFTR* variants. Comprehensive clinical and functional analysis of 159 variants that achieved a frequency of 0.0001 (0.01%) revealed that only 127 (80%) could be definitively assigned as CF-causing.[10] Of the remaining 32 variants, 12 (7.5%) lacked clinical and functional evidence to be CF-causing, while the remaining 20 could not be assigned. The latter group consisted of variants that had varying clinical consequence (VCC) and a few variants of uncertain significance (VUS) that lack sufficient clinical or functional evidence to be assigned. The *CFTR*2 project has undertaken a second round of data collection, thereby increasing enrollment to almost 90,000 individuals with CF from 40 countries, of which 69,745 were alive in 2015. The additional clinical data, along with more extensive functional analysis of variants that affect *CFTR* splicing, have allowed for the assignment of disease status to 306 variants (272 CF-causing, 19 VCC, non-CF causing, and 3 VUS as of August 2016; http://www.cftr2.org).

The functional consequences of CF-causing variants have historically been grouped into five (or six) classes that are described as follows.[80,81] Variants that have consequences that do not fall into one of the five classes are discussed at the end of this section. This scheme has proven useful for relatively coarse correlation with disease severity in the lung, pancreas, and sweat gland.[82–85] However, a number of variants, including F508del, display effects on *CFTR* that fall into two or more of these classes.[86] Recognizing that variants can have multiple effects is important for optimizing *CFTR*-targeted treatments.[12]

Class I variants cause changes in the synthesis of *CFTR* by affecting *CFTR* transcription. These variants manifest their effect within the nucleus and usually involve the processing of transcripts. In most cases, the introduction of a premature termination codon, whether by a change of a codon to a nonsense variant or by frameshift, results in degradation of the transcript by a nonsense-mediated mRNA decay mechanism.[87] G542X (HGVS p.Gly542X) is an example of this type of variant.[88] In some cases, the premature termination codon does not lead to nonsense-mediated decay, and a truncated but nonfunctional protein is produced (e.g., R1162X [HGVS p.Arg1162X]).[89,90] A third consequence of nonsense variants is that they can cause skipping of the exon in which they occur.[91] An example of this phenomenon is seen with the R553X (HGVS p.Arg553X) variant.[92] Variants in the highly conserved splicing signals 5′ and 3′ of exons invariably lead to a loss of full-length transcript due to exon skipping.[93] Loss of exons can also cause a shift in the reading frame, leading to the introduction of a premature termination codon and subsequent RNA degradation. In each case, these types of variants lead to complete, or almost complete, loss of functional *CFTR* protein and produce a classic form of CF (Fig. 49.1). Some of the nonsense variants in *CFTR* have been shown to be rescued in cell lines with application of aminoglycoside antibiotics that can induce read-through of premature termination codons. Atalauren (PTC124), an investigational drug reported to suppress termination codons in some studies but not others,[94,95] is in phase III clinical trials in CF worldwide. The premature termination codon mutants are relatively frequent in Israel, where early phase clinical trials with Ataluren have shown some promise,[96,97] whereas a double-blind placebo controlled phase III study did not show improvement in lung function.[98]



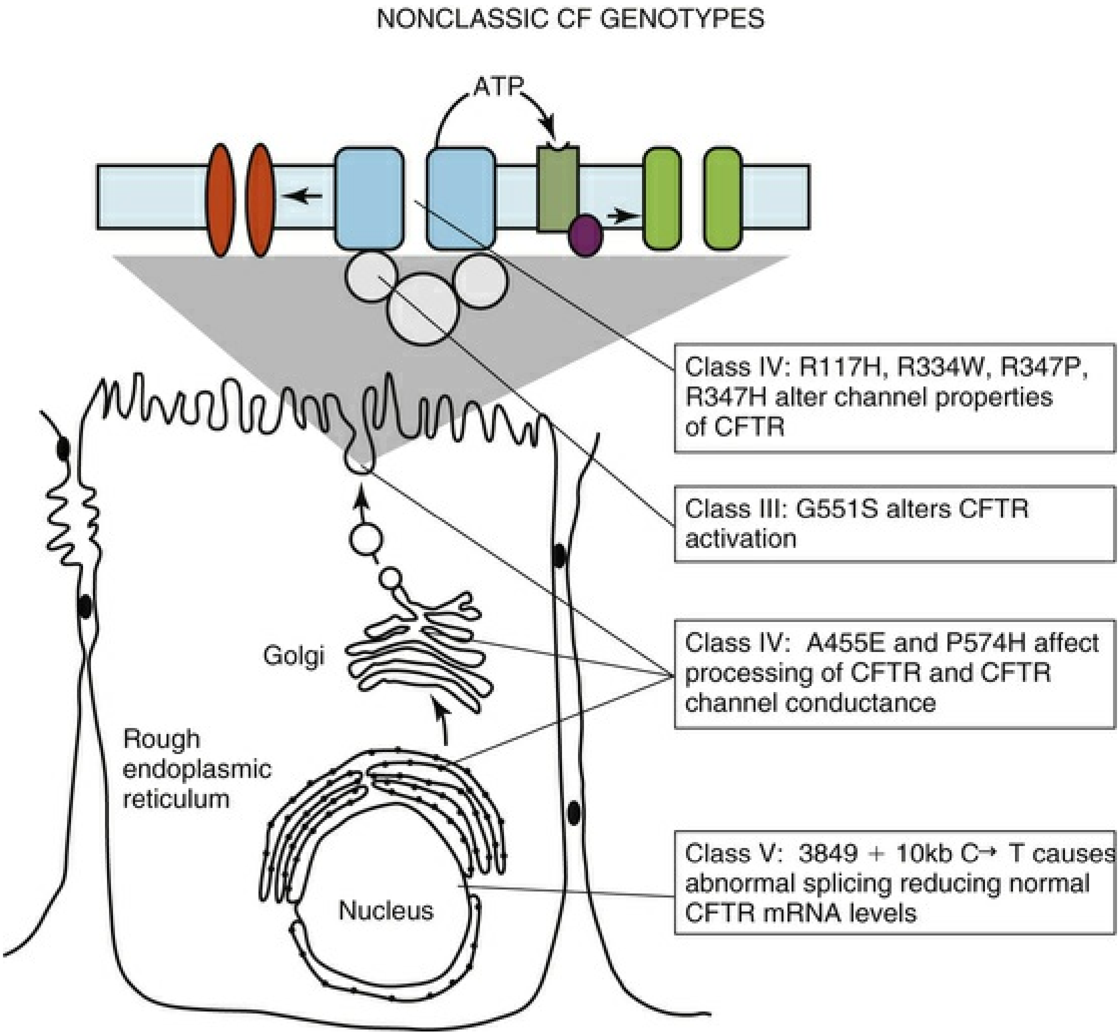
CLASSIC CF GENOTYPES
ATP
Class III: G551D is present in the plasma membrane, but disrupts activation of the CFTR channel and CFTR regulation of the ORCC
Golgi
Class II: ΔF508 has a decreased chloride conductance, is misprocessed and degraded from RER, and is absent from plasma membrane
Rough endoplasmic reticulum
Class I: R553X and W1282X cause severe reduction in mRNA transcript and absence of CFTR protein
Nucleus

**FIG. 49.1** Functional consequences of severe classic variants leading to pancreatic insufficiency. *ATP,* Adenosine triphosphate; *CFTR,* cystic fibrosis transmembrane conductance regulator; *mRNA,* messenger RNA; *ORCC,* outwardly rectifying chloride channel; *RER,* rough endoplasmic reticulum.

The second class of variants involves those that affect the processing of *CFTR* (see Fig. 49.1).[99] A prime example of a class II variant is F508del. Loss of the phenylalanine residue at codon 508 within the first nucleotide-binding fold leads to a misfolding of *CFTR.*[100] Misfolded *CFTR* is recognized by chaperones that shunt the misfolded protein to degradation pathways.[101] The folding defect can be partially overcome by reduction in temperature. Cells grown at 21°C instead of 37°C can produce properly folded *CFTR.*[102] Folded *CFTR* bearing F508del is functional in the cell membrane, but it is not stable and is more rapidly removed from the membrane than its WT counterpart.[103] Because F508del is found in at least 70% of CF patients, the mechanisms underlying *CFTR* degradation have been studied intensively, in hopes of finding approaches that permit *CFTR* bearing the F508del variant to evade degradation (see Chapter 53). Other class II variants have been found that reduce folding efficiency, resulting in a small amount of properly folded functional *CFTR* at the cell membrane.[104,105] Two new molecules have been developed for correction (lumacaftor) and potentiation (ivacaftor) of the F508del mutant protein.[106,107] Phase III clinical trials demonstrated that the two drugs in combination produce improvement in lung function, decrease in pulmonary exacerbations, and increase in body mass index in CF patients homozygous for the F508del variant.[12,108,109]

Disease-associated variants in class III affect the regulation of *CFTR* (see Fig. 49.1). Binding of ATP to the NBDs is required to activate *CFTR.* Variants that affect *CFTR* interaction with ATP have been shown to alter its function.[72,110] An example is the G551D (HGVS p.Gly551Asp) variant, in which the glycine (G) at codon 551 is substituted with aspartic acid (D). The G551D variant severely affects interaction with ATP, creating a form of *CFTR* that is properly folded and inserted in the cell membrane, yet unable to be activated.[100,111] Multiple clinical trials of individuals carrying at least one *CFTR* gene with the G551D variant show that the novel drug ivacaftor (Vertex compound VX770) is safe and produces substantial improvements in lung function, reduction in sweat chloride concentration and infection with *P. aeruginosa,* and increase in body mass index.[112–118] Since G551D affects the gating behavior of *CFTR,* variants that have similar function effects on *CFTR* have been tested for response to VX770. A group of "gating" variants that respond to VX770 in cell-based studies showed significant clinical response in vivo.[119] These results suggest that the hundreds of *CFTR* variants without current approved treatment might be grouped according to functional effect and cellular response to drugs, so-called theratypes.[120] Such an approach could expedite the use of approved drugs for the many *CFTR* genotypes carried by CF patients.

Class IV variants alter the chloride conduction properties of *CFTR,* and in some cases affect the magnitude and the ion selectivity of the channel pore.[121,122] Most class IV variants occur in the transmembrane domains. Since class IV variants may reduce but do not eliminate the flow of ions, some *CFTR* function is preserved (Fig. 49.2), which in turn leads to a milder phenotype or a nonclassic form of CF. However, by the same token, it is recognized that altering this property of *CFTR* produces CF. Thus loss or alteration of the chloride channel function of *CFTR* is key to the development of the CF phenotype, demonstrating that a defect in chloride transport is the primary abnormality in cells of CF patients.



NONCLASSIC CF GENOTYPES
ATP
Class IV: R117H, R334W, R347P, R347H alter channel properties of CFTR
Class III: G551S alters CFTR activation
Golgi
Class IV: A455E and P574H affect processing of CFTR and CFTR channel conductance
Rough endoplasmic reticulum
Class V: 3849 + 10kb C→ T causes abnormal splicing reducing normal CFTR mRNA levels
Nucleus

**FIG. 49.2** Functional consequences of variants leading to nonclassic (mild) forms of cystic fibrosis. *ATP,* Adenosine triphosphate; *CFTR,* cystic fibrosis transmembrane conductance regulator; *mRNA,* messenger RNA.

Class V variants are also associated with a milder form of CF, because they can also result in the production of a reduced amount of normally functional protein (see Fig. 49.2). An example of the latter type of variant is 3849 + 10 kbC > T (HGVS c.3717 + 12191C > T). This variant occurs within intron 22 (legacy intron 19), approximately 10 kilobases from the nearest splice site of exon 22, and leads to the aberrant splicing of *CFTR,* a nonfunctional protein.[123] However, the aberrant splicing mechanism is incomplete, and a small amount of normally spliced *CFTR* transcript is made, leading to the synthesis of some normal *CFTR* and a CF phenotype that is moderate in severity.

CF-causing variants have been shown to affect other functions of *CFTR. CFTR* regulates other ion channels, such as the ENaC and the ORCC.[124] Variants in the first NBD have been shown to variably affect *CFTR* regulation of these channels.[125,126] Variants in the N terminus or in the C terminus of *CFTR* can affect the trafficking, membrane insertion, or stability of *CFTR.*[127,128] These genotypes are sometimes classified as class VIA or VIB. Finally, variants in ENaC have been shown to cause cases of atypical CF.[129,130]

## Clinical Consequences of Variants

Correlation of the *CFTR* genotype with the CF phenotype has been investigated using three methods. In genotype-driven studies, patients are grouped according to genotype, and clinical features are compared. When patients who were homozygous for the F508del variant were compared with patients who carry one copy of F508del and a different CF variant, it was shown that a number of the less common variants produce the same degree of disease severity as the F508del variant.[131] Some variants cause less severe organ disease, or disease in a subset of organ systems affected in classic CF, resulting in a “nonclassic” CF phenotype.[132] The *CFTR* genotype demonstrates a consistent association with the severity of pancreatic disease.[133] A less consistent correlation has been noted with abnormalities in sweat chloride concentration.[134] However, only one variant, A455E (HGVS p.Ala455Glu), has been unequivocally correlated with severity of lung disease.[135,136] A few other variants, particularly those in class IV and V, may associate with less severe lung disease.[137] In the phenotype-driven method, *CFTR* variants are identified in patients grouped according to disease severity. This approach has identified relatively uncommon variants that are associated with nonclassic forms of disease.[138–141] A third approach has been to correlate the class of variant with the severity of disease. Those who carry variants that cause a complete or nearly complete loss of function, such as class I, II, and III variants, usually manifest classic CF. Variants that permit some residual function, such as those in classes IV and V, have been associated with milder phenotypes usually associated with pancreatic sufficiency.[134,137,142] However, it is important to recognize that many exceptions exist. For example, *CFTR* containing A455E affects the processing of *CFTR* (class II) but is associated with pancreatic-sufficient CF and milder lung disease.[104,105]

Diagnosis of atypical forms of CF can be difficult, especially when one or more alleles fails to demonstrate a disease causing variant.[143,144] Sweat chloride may be normal in some combinations of CF genotypes, making the test less reliable for nonclassic CF. Standardization of protocols to measure nasal epithelial chloride and sodium transport has proven useful in the diagnosis of CF.[145,146] The nasal potential difference (NPD) test can detect both classic and nonclassic forms of the disease,[147] and has been a secondary outcome measure in clinical trials of ataluren, VX809, and VX770.

# Pathophysiology

CF is caused by the reduction or dysfunction of the *CFTR*, a cAMP-regulated chloride and bicarbonate channel and a master regulator of other ion channels that coexist in the apical membranes of cells lining the airways, sweat glands, hepatobiliary system, and reproductive tracts. In the absence of disease, *CFTR* activity downregulates or tempers the sodium absorption through ENaC.[148,149] In CF, the combination of a reduction in chloride transport and unregulated excessive sodium transport leads to the classic ion and water hydration defects that occur in the pancreas and vas deferens in utero, and the airways, biliary tract, intestines, reproductive tracts, and sweat glands after birth. *CFTR* is also expressed in other organs that do not succumb to disease, such as the heart and kidneys. Abundant alternative channels exist in those tissues to compensate for lack of *CFTR*-mediated chloride transport.[33,150,151]

## Airways Dehydration and Disruption of Mucociliary Clearance

Airway surface liquid (ASL) bathes the cilia of the upper airway, and the depth and composition of this fluid is regulated by *CFTR* and ENaC. In CF, the ASL height is reduced and cilia are less efficient at moving particles and mucus.[152] Secondary effects of *CFTR* dysfunction include abnormal mucus secreted by the submucosal glands and epithelial cells. The blanket of airway surface mucus becomes excessive, but does not help eradicate bacteria that colonize and inflame the CF airways.

*CFTR* controls both the ENaC and the ORCC. When *CFTR* is absent, the ORCC cannot secrete chloride, amplifying the secretion defect.[153] The calcium-activated chloride channel (CaCC) and the pH-activated ClC-2 coexist and are independent of *CFTR*.[154–160] The latter are therapeutic targets in CF. A phase III program testing aerosolized denufosol, which activates the CaCC through binding to P2Y2 receptors and increasing intracellular calcium, failed to improve lung function over 1 year. It is yet unclear whether activation of an alternative chloride secretion pathway will be sufficient to overcome the defects associated with classic CF.

CF airways quickly become colonized with bacteria after birth. Defective mucociliary clearance likely plays a major role, but additional defects in bacterial clearance related to the importance of *CFTR* in the lipid raft region of the plasma membrane are emerging.[161–164] Inflammation in response to bacterial colonization is excessive and ineffective.[165,166] The ASL becomes infiltrated with neutrophils that respond to IL-8 secretion. As the neutrophils die, they liberate their DNA, which contributes to the viscosity of the mucus. Aerosolized DNase thins this mucus and improves lung function. Aerosolized hypertonic saline also facilitates clearance and improves lung function by a different mechanism.

# Cystic Fibrosis Animal Models

CF research is perhaps the only field that benefits from having five mammalian genetic animal models, including the mouse,[167] rat,[168] rabbit, ferret,[169] and pig.[170–171] While the phenotype of the CF rabbit model has not been published, scientists have learned much from the differences and similarities between species. Broadly speaking, phenotypes can be broken down into lung, gastrointestinal (intestine, pancreas, liver, and gallbladder), and reproductive (vas deferens).

## Lung Phenotypes

With more than two decades of research on CF mice of various *CFTR* genotypes, the general consensus is that they have a negligible or mild lung phenotype[172–174] Early research implicated a CaCC in the airways of mice as compensating for the lack of *CFTR*.[175] More recent research has suggested that *CFTR* counterbalances H+ secretion through the H+/K+ exchanger ATP12A, which acidifies ASL and impairs innate immunity in CF humans, but not mice, due to the differential expression of this exchanger.[176] Despite the lack of a robust lung phenotype in CF mice, there is evidence that they have a hyperinflammatory phenotype when challenged with pseudomonas-laden agarose beads.[177] While the CF rat model is relatively new, it does not develop a spontaneous bacterial colonization phenotype in the lung, despite having a reduced ASL volume and a reduction in submucosal gland mass.[168]

The lung phenotype in CF ferrets[178,179] and pigs[180] is considerably more robust than in CF rodents and clearly demonstrates similarities to the CF human phenotype.[181] When challenged with bacteria, both newborn CF pigs and ferrets have impaired antibacterial killing in comparison to non-CF animals.[180,182] Interestingly, impaired innate immunity in newborn CF ferrets appears to be selective for *P. aeruginosa*,[182] despite the fact that other species of bacteria colonize the lung later in life.[178] Studies in CF pigs have suggested that the lack of *CFTR*-dependent bicarbonate secretions leads to a reduced ASL pH, and that this impairs bacterial killing at the airway surface.[183] By contrast, impaired antibacterial killing of ASL from CF ferrets is unaltered by bicarbonate.[182] Unlike CF pigs, the lungs of newborn CF ferrets are rapidly colonized by bacteria after birth and die within the first week of life if not reared on antibiotics.[179] These differences in early innate immunity between CF pigs and ferrets may be due to the fact that ferrets postnatally develop submucosal glands and ciliated cells, whereas pig airways are fully developed at birth. By a week of life, mucociliary clearance rates decline in CF as compared with non-CF ferret airways as ciliogenesis increases.[182] There remains a debate as to whether the ASL is dehydrated in these CF models with supporting evidence in the ferret[182] and pig[184] models using microoptical coherence tomography and other refuting evidence in the pig model using histologic endpoints.[185]

Inflammation in the CF lung is thought to be an important component of the disease process, with evidence in CF mice for a hyperinflammatory phenotype.[177] While inflammation is not observed in the newborn CF pig lung,[180] newborn CF ferret lungs have elevated IL-8 and TNF$\alpha$ and reduced IL-1β in the bronchoalveolar lavage fluid (BALF), despite having no differences in bacterial load as compared with non-CF animals.[182] While sterile BALF harvested from breathing C-sectioned ferrets lacked genotype-specific differences in these cytokines, IL-8 induction in the BALF of naturally born as compared with C-section animals was only observed in CF animals,[182] suggesting that first bacterial exposure to the lung induces IL-8 in the absence of *CFTR*. Interestingly, proteomics analysis of CF and non-CF newborn and C-section BALF suggests that certain pathways that control immunity and inflammatory (including the complement system, macrophage functions, mammalian target of rapamycin signaling, and eukaryotic initiation factor 2 signaling) are repressed in the naive CF ferret lung, and that these pathways are accentuated at birth following exposure to bacteria[182] Similarly, gene expression array studies on 15-day-old CF ferret lungs demonstrate significant elevations in IL-8-mediated inflammatory pathways.[186] More recent transcriptome analysis of newborn CF pig lungs challenged with heat-killed bacteria also suggests dysregulation of acute inflammatory responses, as compared with non-CF littermates.[187]

## Gastrointestinal Phenotypes

The intestine, pancreas, liver, and gallbladder are all adversely affected in CF, although the penetrance of clinically apparent disease varies for each of these organs. All CF animal models have intestinal disease that manifests either in utero (ferret and pigs) or at weaning (mice and rats). Meconium ileus, an in utero complication of gut obstruction, is observed in ~15%–20% of CF patients.[188] The incidence of meconium ileus is higher in CF ferrets (75%)[179] and pigs (100%),[189] while CF mice and rats generally manifest gut obstruction at weaning.[168,172] Genetic modifiers of meconium ileus have been identified in CF humans,[190] and this also appears to occur for meconium ileus in CF ferrets[179] and gut obstruction at weaning in CF mice.[191] Juvenile CF ferrets also present with other intestinal CF phenotypes, including rectal prolapse and distal intestinal obstruction syndrome (DIOS).[192]

Exocrine pancreatic disease has a significant impact on the health of CF patients, with ~85%–90% being pancreatic-insufficient within the first 2 years of life.[193] CF animal models have a diverse range of exocrine pancreas phenotypes.[194] CF rodents (mice and rats) generally lack apparent disease in the exocrine pancreas,[168,172–174] and in mice this is thought to be due to an alternative CaCC that compensates for the lack of *CFTR*.[175] Disease of the exocrine pancreas begins in utero in CF pigs, with significant acinar cell atrophy and pancreatic remodeling by birth.[195] In contrast, CF ferrets are born with minor abnormalities of pancreatic histopathology[179] but have progressive loss of acinar cells within the first month of life.[192] While nearly all CF ferrets are born pancreatic-insufficient, with impaired growth and a lack of fecal elastase in the stool, a small percentage of CF ferrets have been found to be pancreatic-sufficient with normal growth and fecal elastase present in the stool.[192] Such findings suggest that genetic modifiers of pancreatic disease also exist in this species. However, it has not been possible to capture this pancreatic-sufficient phenotype through breeding to date, suggesting that multiple genetic modifiers may be responsible. The progression of exocrine pancreatic disease in CF ferrets occurs within the first several months of life and is associated with a robust inflammatory and fibrotic response that transitions to adipogenic remodeling by 3 months of life.[192,196,197]

Liver abnormalities are not uncommon in CF patients and are characterized by biliary cirrhosis (25%), hepatic steatosis (30%), and clinical cirrhosis (5%).[198–200] These disease processes are considerably more variable in CF animal models. Both CF mice and rats lack major pathologies in the liver,[168,172–174] and CF ferrets also lack signs of liver disease at birth.[179] However, with age, ferrets develop variable signs of steatosis, necrosis, biliary hyperplasia, and biliary fibrosis in ~39% of animals.[192] Newborn CF pigs demonstrate evidence of focal biliary cirrhosis[189,201] and a reduced pH of bile collected from the biliary ducts.[202]

Gallbladder disease occurs in ~30% of CF patients.[203] While both the CF mouse and ferret gallbladder lack cAMP-inducible chloride currents indicative of *CFTR*,[173,204] they have grossly different histopathology. In CF mice, the extent of gallbladder disease is quite variable, with some backgrounds showing evidence of decreased size and inflammatory infiltrates.[173] Although newborn CF ferrets demonstrated little gallbladder pathology,[179] as CF ferrets age, they develop significant mucous plugging and mucosal proliferation (~80%–90%).[192] CF pigs have the most severe gallbladder disease, presenting with a microgallbladder at birth.[189,201] Interestingly, rats lack a gallbladder, and thus CF-associated disease in this organ is irrelevant in this species.

## Vas Deferens Phenotype

Nearly all male adults with CF suffer from infertility caused by bilateral absence of the vas deferens.[205] While CF male mice have normal fertility,[173] newborn CF rats,[168] ferrets,[179] and pigs[206] lack a vas deferens bilaterally and thus appear to model this component of the human disease.

## Cystic Fibrosis-Related Diabetes

Cystic fibrosis-related diabetes (CFRD) is a common complication of CF and affects 20%–25% of adolescents and 40%–50% of those older than 30 years of age[207,208] There have been several reports suggesting that *CFTR* plays a functional role within the beta-cell to facilitate insulin secretion.[209–211] Furthermore, chemical-induced killing of beta-cells in CF mice exacerbates islet cell dysfunction and leads to an altered inflammatory response.[212,213] By contrast, other findings have suggested that CF mice harboring the F508del-*CFTR* variant do not have an intrinsic beta-cell secretory defect, but rather acquire insulin resistance and a reduced beta-cell mass with age.[214] Interestingly, lung bacterial clearance in diabetic CF mice, following streptozotocin (STZ)-induced beta-cell injury, is significantly diminished compared with nondiabetic CF mice.[215]

While CF mice appear to have some abnormalities that affect glucose metabolism, their lack of significant exocrine pancreatic disease is likely the reason they do not develop classical CFRD seen in humans. Both CF ferrets and pigs are born with impaired glucose tolerance (IGT).[197,216] IGT in newborn CF pigs appears to be due to a reduced glucose-stimulated insulin secretion.[216] By contrast, IGT in newborn CF ferrets appears to be due to a lack of first phase insulin secretion despite a greatly accentuated later phase.[197] However, the poorly regulated insulin secretion in newborn CF ferrets does not appear to be due to insulin resistance.[197] These early differences in glucose tolerance between the two models are likely due to the more severe exocrine pancreatic damage and islet remodeling at birth in the CF pigs, as compared with CF ferrets.

The CF ferret model has been most extensively studied in terms of CFRD pathogenesis. Isolated islets from newborn CF ferrets have reduced glucose-stimulated insulin secretion due to a heightened level of insulin secretion in the presence of low glucose,[197] demonstrating that islet-intrinsic defects in insulin secretion exist in CF ferrets. This dysregulated insulin secretion by CF ferret islets appears to mirror that seen in nursing newborn CF ferrets and is thought to be a result of the emerging inflammation at birth in the pancreas. Recently, rising pancreatic inflammation in juvenile CF ferrets has been shown to significantly reduce beta-cell mass and lead to spontaneous diabetic-level hyperglycemia at 1–2 months of age, a time at which proinflammatory cytokines (IL-1β, TNF$\alpha$, IL-6, CXCL10) peak in the pancreas.[196] Interestingly, at 2–3 months of age, CF ferrets undergo a rapid recovery in their ability to regulate blood glucose following a meal with a coincident increase in beta-cell mass and islet cell function.[196] This novel finding of productive islet remodeling following peak exocrine inflammation in the CF ferret pancreas was associated with a fibrotic to adipogenic transition, marked by elevation in PDX1, PPARγ, and adiponectin. Such findings suggest that the early CF pancreas has a remarkable ability to repair damaged islets, although formal proof of regenerating beta-cells is still lacking.[196] Despite this unique "honeymoon" period observed in CF ferrets following glycemic crisis, with age they go on to develop the more classically studied CFRD phenotype in CF patients with impaired insulin secretion in response to hyperglycemic clamp and to arginine. However, insulin sensitivity was normal, as measured by using a euglycemic hyperinsulinemic clamp.[196] An interesting clinically relevant observation from this study was that mixed meal tolerance was impaired at all ages in CF ferrets, while oral glucose intolerance was not detected until 4 months.

# Characteristics of Systemic Disease

## Airways, Upper and Lower

Lung disease remains the major expression of morbidity and mortality in CF. Infants with CF are born with normal lungs, and pulmonary disease develops over a variable time course. The earliest lesion is obstruction of the small airways by abnormally viscous airway mucus. A secondary bronchiolitis with plugging of the airways invariably follows and develops into bronchiectasis as the respiratory epithelium becomes chronically infected. A striking feature of CF lungs is that the parenchyma is virtually untouched for much of the course, while the airways are severely afflicted. The airways become a reservoir for chronically infected mucopurulent secretions, first by *Staphylococcus aureus* and *Haemophilus influenzae,* and later by a distinctive mucoid form of *P. aeruginosa.* Once mucoid *P. aeruginosa* colonizes the lungs, it is virtually impossible to eradicate. Emergence of methicillin-resistant strains of *S. aureus* (MRSA) is increasing and a cause for concern.[217] Respiratory failure is the major cause of death, with the median life span now increased to 41.6 years in the United States (Cystic Fibrosis Foundation Registry Data, 2015).

The respiratory disease is usually progressive, with superimposed acute exacerbations. Cough is an early symptom and may be nonproductive and mistaken for asthma. Production of sputum develops and is an indicator of chronic inflammation and infection. A typical course is characterized by intermittent acute pulmonary exacerbations, in which there is an increased volume of sputum, a change in the color of sputum, decreased exercise tolerance, and weight loss. Digital clubbing is a universal finding with progression of the lung disease. The chest radiograph becomes abnormal early in the course of the disease and demonstrates hyperinflation (Fig. 49.3) and patchy atelectasis (Fig. 49.4). The chest computed tomography (CT) scan is even more sensitive to changes (Fig. 49.5) and may be preferred over the chest radiograph for a quantitative assessment of progression of lung disease.[218] Bronchiectasis develops from progressive chronic infection and destruction of the airways (Fig. 49.6). Pulmonary function tests early in the disease reflect small airways obstruction but then progress toward a decrease in the forced expiratory volume in 1 second ($FEV_1$) and increases in residual volume, functional residual capacity, and the ratio of residual volume to total lung capacity. The vital capacity is eventually reduced. With treatment of the acute exacerbations, variable improvements in some of these lung functions can be documented.

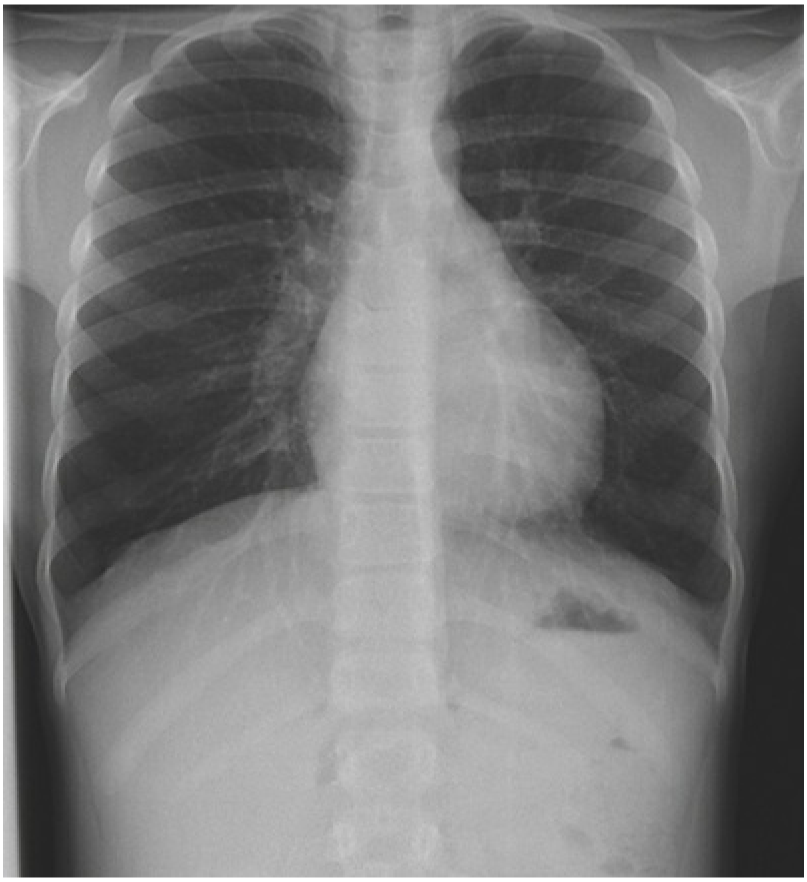


**FIG. 49.3** Chest radiograph of a 10-year-old female with cystic fibrosis (genotype F508del homozygous) who complained of increasing cough and sputum production. Both lung fields are hyperinflated, and there are increased lung markings. Expectorated sputum culture grew nonmucoid *Pseudomonas aeruginosa.*

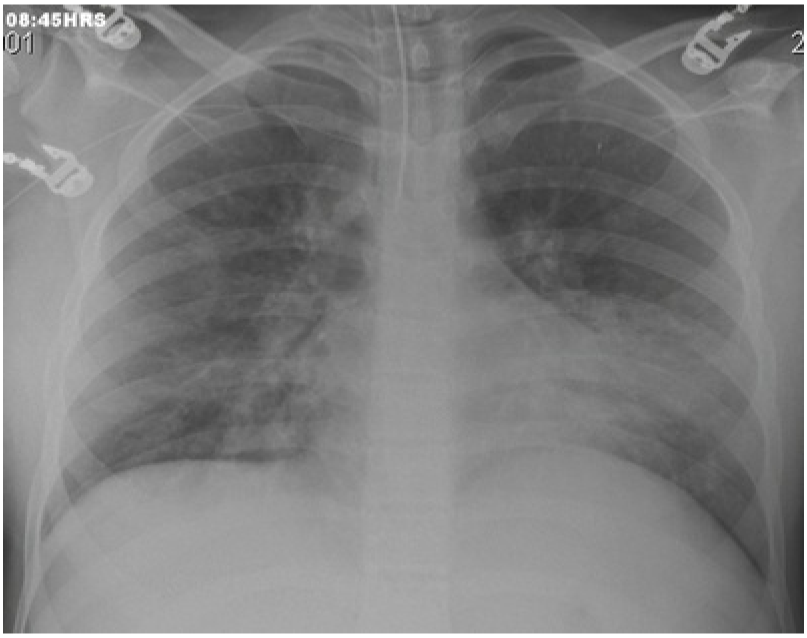

**FIG. 49.4** Chest radiograph at bronchoscopy of an adolescent female with cystic fibrosis (genotype F508del/621 + 1G) who complained of sudden and transient chest pain on the left side, followed by an increase in cough. There are lingular, right lower, and right middle lobe infiltrates and atelectasis. Lung fields improved after 14 days of intravenous antibiotics directed against the *Staphylococcus aureus* and mucoid *Pseudomonas aeruginosa* that grew from bronchoalveolar lavage fluid cultures.

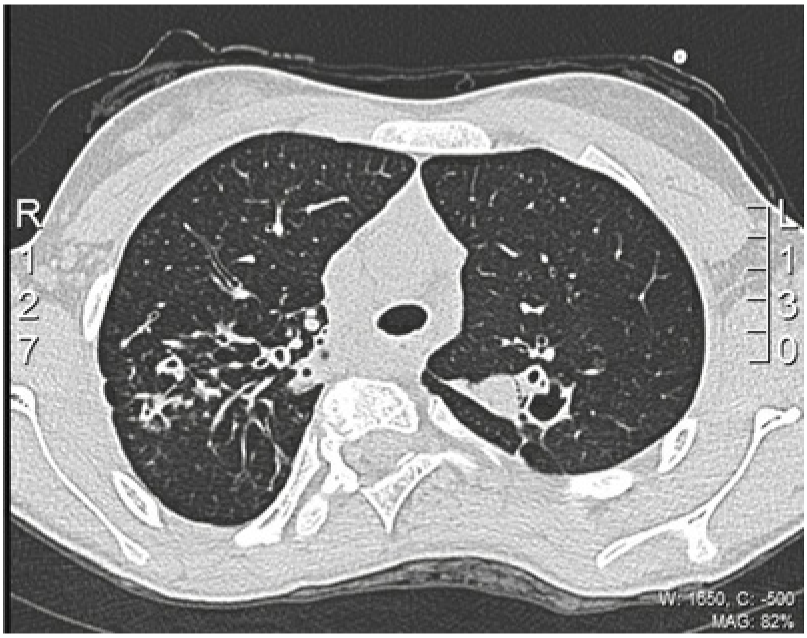

**FIG. 49.5** Spiral chest computed tomography scan of an adolescent female with cystic fibrosis (genotype F508del homozygous) and a slight decline in forced expiratory volume in 1 second. There is bilateral upper lobe bronchiectasis. Her sputum cultures grew *Pseudomonas aeruginosa* and methicillin-resistant strains of *Staphylococcus aureus* (MRSA).

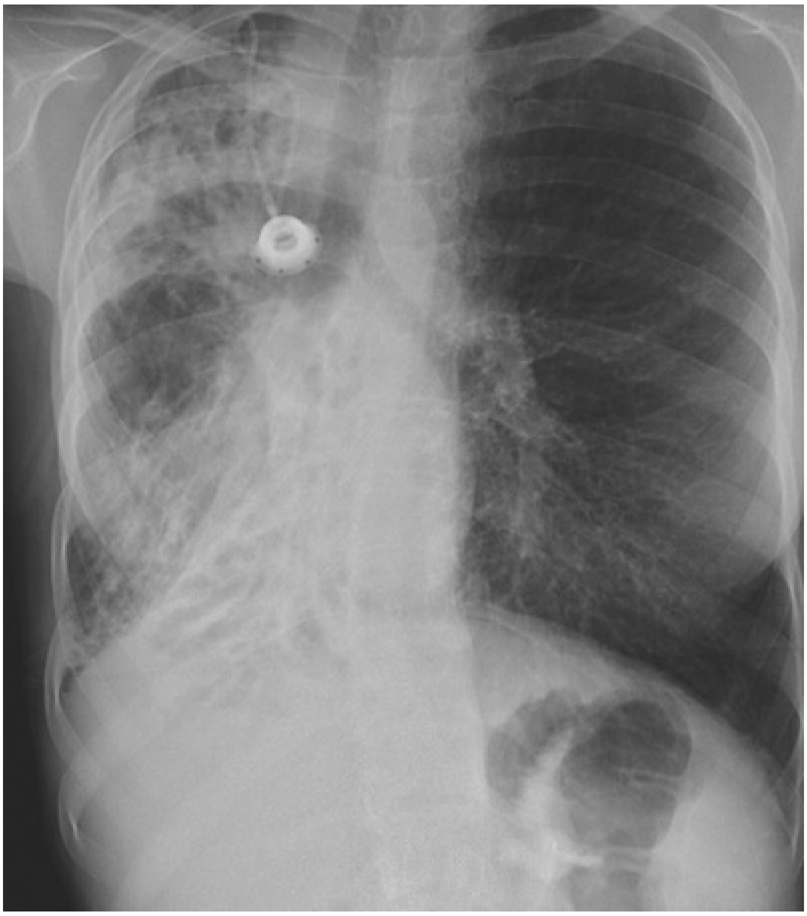

**FIG. 49.6** Chest radiograph of a 16-year-old female with cystic fibrosis (genotype F508 homozygous) and recurrent pulmonary exacerbations. The left lung shows hyperaeration and bronchial wall thickening. The right lung shows decrease in volume, bronchial wall thickening, and bronchiectasis. Sputum cultures grew *Achromobacter xylosoxidans.*

The upper airway is also severely affected in CF. Chronic pansinusitis is found in more than 99% of patients with CF, due in part to mucous gland hyperplasia, abnormal chloride ion transport by the sinus epithelial cells, and colonization with bacteria. Chronic sinusitis may contribute to infection of the lower respiratory tract by acting as a reservoir of infection. CT scans of the sinuses are useful in assessing the extent of sinus involvement and in the selection of patients who might benefit from a surgical drainage procedure.

Sinus involvement is complicated by nasal polyposis in 6%–40% of patients. Nasal polyps should be suspected if nasal airflow is obstructed, the nasal bridge widens, or there is persistent epistaxis, loss of taste, or loss of appetite. Polyps appear in childhood and often recur after initial resection. If the disease is left untreated, serious bony erosions can occur. Medical management consists of topical glucocorticoids, macrolide antibiotics for their antiinflammatory action, antibiotics to cover the organisms in the sinuses, and surgical approaches.[219]

## Inflammation

A particularly intense inflammatory state appears early in the CF airways. Konstan and colleagues[220] demonstrated that the inflammatory infiltrate is predominantly neutrophilic. BALF studies in infants suggest that inflammation may even precede colonization with bacteria, although this is controversial.[221,222] If inflammation is both a primary defect related to dysfunctional *CFTR* and a result of infection, then antiinflammatory therapy may be helpful.

Immune-mediated inflammation contributes significantly to the lung damage present in patients with CF. Specific antipseudomonal antibiotics do not eradicate the organism permanently. Despite aggressive intravenous therapy with large doses of increasingly more potent agents, colonization proceeds. Chronic infection then elicits recruitment and activation of neutrophils in the airways. The neutrophils release proteases such as granulocyte elastase and cathepsin G. This protease burden has been associated with both destruction of the lung matrix and cleavage and inactivation of a variety of opsonins. There is also evidence of immune complex formation in CF patients that correlates with disease severity and prognosis.

## Infection

Nonencapsulated *H. influenzae* often colonizes the oropharynx of the young child with CF. Although it is not considered a serious pathogen, rising antibody titers to *H. influenzae* have been detected.[223] *S. aureus* is the most frequent organism detected initially on oropharyngeal cultures, and it is still debated whether chronic antibiotic prophylaxis against this organism is useful. The acquisition of MRSA is increasing and emerging as a potential pathogen in communities of both CF and healthy children. Nonmucoid *P. aeruginosa* is acquired at varying times after birth, and transformation to a mucoid phenotype is associated with increased inflammatory burden and sputum volume. Early intervention strategies and chronic antibiotic protocols are aimed at eradicating or reducing the infection for as long as possible. *Burkholderia cepacia* complex (composed of nine different species) is particularly feared. Genomovar III is highly virulent and transmissible, and can be associated with a sepsislike condition that markedly reduces survival. Transient colonization with a *B. cepacia* spp. is becoming more common.

With more aggressive antibiotic strategies in place and frequent sputum and oropharyngeal cultures, a number of multiply resistant organisms are being identified. *Stenotrophomonas maltophilia, Alcaligenes xylosoxidans,* and nontuberculous mycobacteria alone or in combination with *P. aeruginosa* or *S. aureus* are challenging clinicians.[224] The complexity of microbial communities suggests that diversity is lost with aging in CF, but traditional culture methods are inadequate to completely catalog the totality of microbes. Antibiotic exposures shift microbial composition, and recovery postexposure may be incomplete.[225] Efforts in antibiotic stewardship are ongoing to prevent increasingly resistant organisms.

Additional details pertaining to bacterial, viral, and fungal pathogens in CF are discussed in Chapter 51. An extremely important message to learn from this work is that infection control strategies in the acute care setting, ambulatory clinics, and the home are mandatory if we are to contain the spread of transmissible organisms.[226]

## Gastrointestinal Disease

Gastrointestinal disease begins in utero in the pancreas, where dysfunctional *CFTR* produces a deficiency in exocrine pancreatic secretions because of progressive plugging of the pancreatic ducts by viscous secretions. The combination of the in utero deficiency of proteolytic enzymes with secretion of abnormal mucoproteins by the goblet cells of the small intestine leads to obstruction of the distal ileum by inspissated, tenacious meconium. About 15% of infants with CF are born with intestinal obstruction called meconium ileus. There are associated intestinal complications including small bowel atresia, volvulus, perforation, and peritonitis; alternately, there may simply be delayed passage of meconium and distal colonic obstruction secondary to the meconium plug syndrome.

The loss of pancreatic enzyme activity leads to intestinal malabsorption of fats, proteins, and, to a lesser extent, carbohydrates after birth. Pancreatic function is lost incrementally until complete loss is seen in 85% of patients. Infants manifest poor or absent weight gain, chronic abdominal distention, absence of subcutaneous fat and muscle tissue, steatorrhea, and rectal prolapse. Paradoxically, the untreated child may have a voracious appetite, but the caloric intake is insufficient to meet daily needs.

In older individuals, intestinal mucous gland hyperplasia is associated with abnormal mucins and slowing of intestinal transit time. If pancreatic enzyme replacement is inadequate, fecal impaction or DIOS can result.

Children, adolescents, and adults with residual pancreatic function may develop recurrent episodes of pancreatitis. Serum and urine amylase and serum lipase are elevated. Attacks can be precipitated by a fatty meal, alcohol, or tetracycline. Patients with one or more class IV or V variants tend to have residual pancreatic function and to be at risk.

Liver disease can result from biliary tract obstruction and inflammation. Normally, *CFTR* is found on the apical membranes of biliary tract cells where chloride transport facilitates bile flow. In CF, focal biliary cirrhosis appears in 10%–20% of infants by 1 year and in up to 80% of adults.[227,228] Little is known about the pathogenesis of liver failure in CF, or why some individuals escape significant injury. Therapeutic intervention is limited to dietary bile salts to reduce biliary sludging.

## Sweat Gland Effects

The gold standard for diagnosis of CF for many years has been the demonstration of elevated chloride and sodium in sweat collected by quantitative pilocarpine iontophoresis. Although no histopathologic changes can be found in the CF sweat gland, the function is abnormal as a result of inadequate reabsorption of salt by the distal collecting duct. The CF sweat is isotonic with plasma, and the skin of affected infants has been described as tasting “salty.” Heavy exercise in hot, humid climates can lead to increased salt losses and profound clinically significant dehydration.

Sweat production occurs in all individuals, primarily by cholinergic stimulation. Cyclic AMP-mediated sweat secretion is insignificant, which is why sweat can be produced in CF individuals through the cholinergic pathway. Sweat chloride concentrations can sometimes be normal or borderline in people with a mild *CFTR* variant. Thus genetic variant analysis or NPD testing may be required to make the diagnosis.

## Reproductive Tissues

The male reproductive tract is exquisitely sensitive to defects in *CFTR* function. Even carriers of one CF gene can present with isolated male infertility. Azoospermia results from an atretic or absent vas deferens that begins in utero. Most males with CF are infertile because of this mechanism.

# Other Disorders Related to the Cystic Fibrosis Transmembrane Conductance Regulator

## Congenital Bilateral Absence of the Vas Deferens

Male infertility due to obstructive azoospermia is a consistent feature of CF, and it has been estimated that 98% of all males with CF have this condition.[229] One notable exception has been males who carry the 3849 + 10 kbC > T variant, as a substantial fraction are fertile.[230] Male infertility is due to malformation of structures derived from the Wolffian duct reproductive tract, manifesting as atrophy of the vas deferens. The seminal vesicles and associated structures also can be involved.[231] Abnormal development of the male reproductive tract begins in utero and continues in the first year of life.[232] On occasion, only one of the vas deferens is destroyed, while the other remains patent. This reduced-fertility condition is termed *unilateral absence of the vas deferens*. Males with CF produce sperm, although spermatic morphologic abnormalities have been reported.

CBAVD also has been reported in healthy males as an isolated cause of male infertility.[233] It has been estimated that approximately 1 in 5000 males are affected with this condition. Because of the phenotypic overlap between CBAVD and male infertility seen in CF males, investigators analyzed the *CFTR* genes in males with isolated CBAVD and discovered that a high proportion carried CF variants.[234] More recent studies with extensive analysis of the *CFTR* gene indicate that approximately 86% of CBAVD patients carry at least one deleterious variant.[235] F508del is the most common variant, occurring in approximately 44% of the cases.[235] The second most common *CFTR* variant in CBAVD males (32%) is the 5T polymorphism of the intron 9 splice acceptor.[236] The frequency of 5T in the general population (10% carrier rate) posed a question as to how it could be associated with male infertility. Pedigree studies revealed that 5T is inconsistently associated with CBAVD, suggesting that other factors contribute to the disease. The dinucleotide TG tract immediately adjacent to the T tract (see earlier) determines whether the 5T variant produces male infertility in an individual who carries a variant in his other *CFTR* gene.[42,45] The variant R117H (HGVS p.Arg117His) is also quite common in males with CBAVD. Approximately 10% of CBAVD males carry this variant, yet less than 1% of CF patients carry this variant. The 5T variant in intron 8 also plays a role in this phenomenon. The R117H variant has occurred at least twice in human evolution—

once in association with the 5T variant and once in association with the more common 7T variant.[237] Males and females who have a CF variant paired with R117H and the 5T variant invariably have a CF phenotype, while those males who have R117H with the 7T variant usually develop CBAVD, although some cases of CF have been observed.[235,237] Notably, females with this combination of variants have presented with pancreatitis and with a normal phenotype.[238,239]

## Pancreatitis

Pancreatitis is a rare presenting sign of CF in patients with residual pancreatic function.[240] Isolated pancreatitis does not present with similar clinical features to CF. However, the concept that *CFTR* dysfunction may play a role in idiopathic pancreatitis is supported by two observations. First, sweat electrolyte concentrations have been found to be elevated in a subset of chronic pancreatitis patients.[241] Second, *CFTR* is known to be expressed in pancreatic ducts, a major site of disease in pancreatitis. Two studies of patients with idiopathic pancreatitis found an increased frequency of variants in the *CFTR* gene.[238,242] In both studies, the frequency of *CFTR* variants in the patients with pancreatitis was significantly higher than in the control population and higher than the expected frequency in the general population. Several other reports have since confirmed that CF variants occur at a higher frequency in patients with isolated pancreatitis.[243–246] However, it appears that additional genetic or environmental influences are required for the development of pancreatitis.[247] Variants in other genes known to give rise to monogenic forms of pancreatitis, such as the secretory trypsinogen inhibitor gene *ST8SIA4 (PST1),* can combine with *CFTR* variants to increase the risk of developing pancreatitis.[243,244] While nonalcoholic chronic pancreatitis has been associated with CF variants, it is not clear that the risk of developing pancreatitis in the case of alcohol abuse is increased in the presence of *CFTR* variants.[248]

## Sinusitis

Chronic sinusitis is a consistent feature of CF.[240] In addition, some males with CBAVD and *CFTR* variants also have chronic rhinosinusitis.[249,250] Because the sinus epithelium is reliant on *CFTR* function for fluid and electrolyte transport, alterations in *CFTR* could play a role in isolated cases of chronic rhinosinusitis. Indeed, patients who presented with chronic rhinosinusitis to an otorhinolaryngology clinic were found to have a higher frequency of CF variants than disease-free control populations, suggesting that deleterious variants in *CFTR* predispose to the development of sinusitis.[52] Two other studies have found that patients with chronic rhinosinusitis have an increased frequency of CF variants,[251,252] while one study did not find this association.[253] More recently it has been demonstrated that the prevalence of chronic rhinosinusitis in CF carriers is approximately twice the population prevalence.[254] Thus reduction of *CFTR* function by approximately 50% appears to increase the risk of developing chronic forms of sinus disease.

# Diagnosis and Presentation of Cystic Fibrosis

*Colin Wallis MD, MRCP, FRCPCH, FCP, DCH*

A diagnosis of cystic fibrosis (CF) has lifelong implications for affected individuals, their families, and their acquaintances. This important step needs to be taken accurately and early on. A late diagnosis is often preceded by a catalogue of doctor's visits, family anguish, and anger associated with a delay in the initiation of treatment that may have an impact on long-term outcome. Equally disturbing is a small but increasingly documented experience of children, diagnosed as having CF, whom on review—often years later—are found not to fulfill diagnostic criteria.

Many countries have now introduced newborn screening programs for the diagnosis of CF. This has changed the experience of diagnosing CF for both parents and pediatricians.[1,2] Appropriate monitoring of the child's condition and early therapy are introduced, often before the emergence of signs and symptoms traditionally associated with CF.[3,4] Apart from the advantages of early detection through newborn screening, new challenges have arisen from the screening program, including:

1. Uncertainties about the diagnostic label in some infants who,

following a positive screening result, do not fulfill all the criteria for a CF diagnosis[5,6];

2. The recognition of an ever-widening phenotype for an individual with two cystic fibrosis transmembrane conductance regulator (CFTR) mutations, ranging from a traditional CF phenotype, a spectrum of atypical disease forms, and even individuals with no discernible CFTR dysfunction at all and no evidence of end organ disease at the time of assessment[7,8];
3. The recognition that a CF phenotype can emerge and change over time, presenting de novo in adulthood or moving from “atypical” forms to a more classical CF[7,9];
4. The need for pediatricians and adult physicians to remain vigilant in order to diagnose those individuals who may have been missed by the screening process or did not undergo screening.

In this chapter, we will describe the diagnostic criteria for CF, the diagnostic techniques available for assessing the CFTR function, the screening process, and the need to identify and label atypical cases —both screened and clinically detected.

## Diagnostic Criteria for Cystic Fibrosis

In more than 90% of cases, the diagnosis of CF in an unscreened patient arises from a clinical suspicion supported by a test of CFTR function, the sweat test, with genetic testing for CFTR mutation used as confirmatory testing. A Cystic Fibrosis Foundation (CFF) Consensus Panel (United States) synthesized diagnostic criteria for CF.[10] The key features are summarized in Box 50.1. The basic premise of the consensus statement is that CF is a clinical and not a genetic diagnosis, although acknowledging that genetic testing may have a role in sorting out atypical clinical situations. Any such document must be considered a work in progress to accommodate new developments[11,12] and acknowledged shortcomings.[13] The latest version of the consensus guidelines from the CFF is now available online (https://www.ncbi.nlm.nih.gov/pubmed/28129811).

**Box 50.1**

### Diagnostic Criteria for Cystic Fibrosis (Cystic Fibrosis Foundation Consensus Panel)

One or more characteristic phenotypic features consistent with cystic fibrosis (CF):

Chronic sinopulmonary disease
Gastrointestinal and nutritional abnormalities
Salt loss syndromes
Male urogenital abnormalities resulting in obstructive azoospermia

OR

A history of CF in a sibling

OR

A positive newborn screening test result

AND

an increased sweat chloride concentration
or identification of two disease causing CF mutations
or demonstration of abnormal nasal epithelial ion transport.

## Making the Diagnosis of Cystic Fibrosis

A clinician may need to confirm a diagnosis of CF in various settings such as when

1. A patient has one or more suspicious clinical features;

2. A newborn screening program has identified a child at risk for CF;
3. An individual is being examined after the diagnosis of CF in a family member; or
4. Postnatal confirmation is required when an antenatal test has proven suspicious for CF.

## Clinical Suspicion

The majority of unscreened children with CF present with a history of bulky fatty stools, failure to thrive, and recurrent chest infections.[14] Shortly after birth, 10%–15% will present with intestinal obstruction as meconium ileus. However, there is a wide range of less common presenting features (Box 50.2). Any children or adults presenting with suspicious features of CF should be investigated further, even if they have undergone newborn screening. A possible diagnosis of CF in a child with suggestive clinical findings should not be discounted just because the child appears too well or is thought to be too old. Although the diagnosis is established in most children by the age of 1 year—and earlier if screened—in approximately 10% of children the diagnosis is delayed until after 7 years of age.[15] Patients with pancreatic sufficiency and non-Caucasian patients are particularly vulnerable to delays in diagnosis.[16,17]

**Box 50.2**

### Clinical Features of CF at Diagnosis in Unscreened Populations—Grouped According to Age and Approximate Order of Frequency

#### 0–2 Years

Failure to thrive
Steatorrhea
Recurrent chest infections including bronchiolitis/bronchitis

Meconium ileus
Rectal prolapse
Edema/hypoproteinemia/“kwashiorkor” skin changes
Severe pneumonia/empyema
Salt depletion syndrome
Prolonged neonatal jaundice
Vitamin K deficiency with bleeding diathesis

### 3–16 Years

Recurrent chest infections or “asthma”
Clubbing and “idiopathic” bronchiectasis
Steatorrhea
Nasal polyps and sinusitis
Chronic intestinal obstruction, intussusception
Heat exhaustion with hyponatremia
CF diagnosis in a sibling

### Adulthood (Often Considered CFTR-Related Disorder)

Azoospermia/congenital absence of the vas deferens
Bronchiectasis
Chronic sinusitis
Acute or chronic pancreatitis
Allergic bronchopulmonary aspergillosis
Focal biliary cirrhosis
Abnormal glucose tolerance
Portal hypertension
Cholestasis/gall stones

*CF*, Cystic fibrosis.

## The Sweat Test

The sweat test was first described in 1959 and remains a gold standard for the diagnosis of CF.[18] In the appropriate clinical setting, whether the child has entered the diagnostic algorithm via clinical suspicion or newborn screening, a positive sweat chloride test is diagnostic of CF. There are a number of other rare conditions (sometimes single case reports) that have been associated with a positive sweat test, but these are usually clearly distinguishable by their clinical features (Box 50.3).

**Box 50.3**

### Examples of Noncystic Fibrosis Causes of a Positive Sweat Test

Adrenal insufficiency or stress
Anorexia nervosa
Ectodermal dysplasia
Eczema
Fucosidosis
G6PD deficiency
Glycogen storage disease type 1
Human immunodeficiency virus infection
Hypoparathyroidism
Hypothyroidism
Malnutrition from various causes
Nephrogenic diabetes insipidus
Pseudohypoaldosteronism
Chronic arsenic exposure

The standard sweat test (Gibson and Cooke technique) requires skill and care, and should be undertaken by accredited laboratories. Localized sweating is stimulated by the iontophoresis of pilocarpine into the skin. Sweat is collected on filter paper, gauze, or in microbore tubing[19] over a controlled period of time to ensure that the rate of sweating and the total sweat collected are sufficient and standardized. Guidelines for sweat testing procedures and precautions are available in published[20–23] and electronic format (http://www.acb.org.uk/docs/sweat.pdf).

Chloride is the analyte of choice.[24,25] The sodium levels and osmolality of sweat are less reliable and should never be used in isolation. A sweat chloride concentration of more than 60 mmol/L is considered positive, and levels below 30 mmol/L are likely to be in the normal range. This lower limit of 30 mmol/L was previously set at 40 mmol/L in children older than 6 months, but recent consensus guidelines have revised to a chloride level of less than 30 mmol/L for all age groups.[12,26] Results between 30 and 60 mmol/L have traditionally been considered intermediate and require further evaluation. A high proportion of patients with chloride concentrations in this intermediate range will have two CFTR mutations—usually one at least that is not defined as disease causing, a situation found with increasing frequency with the advent of more detailed CFTR mutation testing.[27,28]

Following the introduction of newborn screening (NBS) for CF, sweat tests are increasingly performed on infants. It is recommended that sweat chloride testing in asymptomatic newborns with a positive NBS test be performed when the infant is older than 2 weeks of age and more than 2 kg.[29,30] The vast majority of affected infants will have a chloride level greater than 60 mmol/L. A sweat chloride value between 30 and 59 mmol/L should be considered intermediate and trigger further patient evaluation, including repeat testing when older.[31] Certain CFTR mutations (such as R117H, R334W, 3849+10kbC>T) associated with a milder CF phenotype may also demonstrate a normal sweat chloride.

Some normal adolescents and adults can have sweat chloride values in the intermediate range, and sweat chloride levels alone may be insufficient to diagnose CF in the older adolescent.[32] A false-positive sweat test in the severely malnourished child or the critically ill child in intensive care needs cautious interpretation and follow-up.

Research continues to explore the development of an easier sweat test. Collecting systems such as the Macroduct[33] and Nanoduct[19] simplify collection and are now in routine practice. The role of sweat conductivity as a diagnostic tool in CF is debated.[34] In one large trial, the best conductivity cutoff value to diagnose CF was ≥90 mmol/L, and the best conductivity cutoff value to exclude CF was less than 75 mmol/L.[35] However, most clinicians and laboratories will chose to confirm a positive sweat conductivity result with a formal measurement of chloride concentration.

## Mutation Analysis

The 1989 identification of the CF gene[36] and the characterization of its protein product (CFTR) held the promise that the diagnostic dilemmas for the condition were over. If you had two CFTR mutations, you had CF—if not, you did not. Unfortunately it has not worked out that simply. Even though the presence of two mutations is very supportive of the diagnosis of CF in the appropriate clinical setting, two alterations in the gene that encodes CFTR does not necessarily mean that you will develop classic CF disease, as outlined later.

There are more than 2000 different CF gene mutations documented, although the clinical impact of these mutations is frequently uncharacterized. A valuable online resource lists identified mutations at http://www.genet.sickkids.on.ca/app.

Clinically available techniques do not routinely allow a full screen of the entire CF genome, and most laboratories will only search for the most common mutations within their geographical region—focusing on those known to be disease causing. Examples of disease-causing CFTR mutations are listed in Table 50.1, highlighting the dominance of the ΔF508 mutation (present in >70% of CF alleles in Caucasian populations). Customizing mutation panels to match the patient's ethnic background and clinical presentation can enhance the sensitivity of DNA testing in CF.

### Table 50.1

**Common Mutations That Cause Cystic Fibrosis Listed According to Frequency**[a]

| Traditional Name | HGVS[b] Nomenclature | Frequency (%) |
|---|---|---|
| ΔF508 | p.Phe3508del | 75.0 |

[a] In Caucasian populations—variations in frequency occur between different ethnic groups and geographic regions.

[b] Human Genome Variation Society nomenclature.

Second, there is a range of mutation types that have been classified into classes according to the functional impact on the CFTR.[37,38] The final protein product may be incomplete, complete but incorrectly packaged and processed, or a final CFTR molecule that is unstable or incapable of reaching the cell surface in sufficient quantity to be physiologically effective. This is discussed further in Chapter 49.

In addition to the “disease-causing” mutations, there are also recognizable polymorphisms that do not necessarily result in a clinical phenotype but may influence the structure of the final protein product when associated with another mild mutation. The thymidine run in intron 8 is a well-described example where the 5T allele leads to a substantial reduction in functional protein compared with the 9T allele; the 7T allele is intermediate in its effect. The clinical phenotype associated with two CFTR mutations is far broader than previously anticipated (Box 50.4). Caregivers should avoid making prognostic predictions based on genotype alone.[39] Examples of the potential clinical impact of selected CFTR mutations[39] is shown in Table 50.2 and can also be researched on the CFTR2 website (http://www.cftr2.org/), which also regularly updates the growing list of disease causing mutations.

## Box 50.4

## Examples From the Range of Clinical Features That Can Be Associated With Two Mutations in the CF Gene

"Classical CF" with pancreatic insufficiency
Sinopulmonary disease, pancreatic sufficiency and positive sweat test
Sinopulmonary disease and male infertility with a normal sweat test
Severe sinusitis and congenital bilateral absence of the vas deferens
Male infertility only
Chronic pancreatitis only
Allergic bronchopulmonary aspergillosis
Sclerosing cholangitis
Positive sweat test only
No clinical features including normal sweat chloride.

## Table 50.2

**Examples of *CFTR* Mutations With Regard to Their Clinical Consequences**

| Mutation Group | Examples |
|---|---|
| A. CF-causing | F508del, R553X, R1162X, R1158X, 2184delA, 2184insA, 3120+1G>A, I507del, 1677delTA, G542X, G551D, W1282X, N1303K, 621+1G>T, 1717-1G>A, A455E, R560T, G85E, R334W, R347P, 711+1G>T, 711+3A>G[a], 1898+1G>A, S549N, 3849+10kbC>T, E822X, 1078delT, 2789+5G>A, 3659delC, R117H-T5[a], R117H-T7[a], D1152H[a], L206W[a], TG13-T5[a] |
| B. CFTR-related disorders associated | R117H-T7[a], TG12-T5[a], R117H-T5[a], D1152H[a], TG13-T5[a], S997F, R297Q[a], L997F, M9521, D565G[a], G576A[a], TG11-T5[b], R668C-G576A-D443Y, R74W-D1270N |
| C. No clinical consequences | I148T, R75Q, 875+40A/G, M470V, E528E, T854T, P1290P, 2752-15G/C, I807M, I521F, F508C, I560V, TG11-T5[b] |
| D. Unknown or uncertain clinical relevance | Mainly missense mutations[c] |

[a] Mutations that may belong either to Group A or to Group B.

[b] Mutations that may belong either to Group B or to Group C.

[c] Certain common sequence (missense) variants with subclinical molecular consequences (e.g., M470V) may cosegregate on the same chromosome and exert more potent, cumulative phenotypic effect. Such polyvariant haplotypes could be potentially disease causing.[56]

Failure to find two CF mutations from a selective or extended search does not exclude the diagnosis of CF. There are also rare reports of patients with classical CF symptoms and signs and a positive sweat test who do not appear to have any mutations in the CFTR gene—even when the entire gene has been sequenced—screening all 27 exons and the intron-exon boundaries.[40] These findings suggest that, on these very rare occasions, CF may be caused by mutations within the promoter region of the CFTR gene, in one of the introns, or even in a distant controlling gene from an unrelated locus.[41] This highlights the fact that despite advances in molecular diagnostics, CF remains a clinical diagnosis supported by a functional test of CFTR dysfunction.

An unintended consequence of the newborn screening programs has been the detection of infants who have a high immunoreactive trypsin and, on further assessment, have a normal or borderline sweat test, and in whom the genotyping reveals one or two mutations of uncertain clinical consequence. These children have no clinical features at the time of detection and present a difficult diagnostic conundrum. The classification of the various “types” of CF is discussed at the end of this chapter.

## Assessment for Organ Involvement

To determine the presence of specific organ disease in a patient with the genetic predisposition to develop CF disease, but in whom there are few clinical indicators, may require more detailed and targeted assessment.[42] Examples include the following:

1. Computed tomography scanning of the lungs can be used to evaluate subtle pulmonary changes such as bronchial wall thickening, small airway disease, and air trapping not readily visible on plain radiography.
2. Computed tomography can also be used to evaluate the sinuses, which are invariably opacified in CF patients.
3. Testing for pancreatic function testing can involve

sophisticated tests of pancreatic enzyme measurements from endoscopic sampling or 3-day stool collections for fecal fat analysis. A simple test for quantification of fecal elastase 1 to diagnose pancreatic sufficiency[43,44] has shown considerable sensitivity and reliability and is not contaminated by exogenous enzyme administration.[45] Caution is required in the interpretation of early-life stool samples, especially in the premature infant or newborn within the first few days of life.[46]

4. Sputum, bronchoalveolar lavage fluid, oropharyngeal swabs, or sinus aspirates can be cultured for known CF pathogens. *Staphylococcus aureus* or *Pseudomonas aeruginosa,* although not unique to CF, may support a possible CF diagnosis.
5. Congenital bilateral absence of the vas deferens (CBAVD) is a common finding in many males with CF. Postpubertal males can have semen analysis for azoospermia, or younger males can be assessed with ultrasound for CBAVD.[47]
6. Valuable information can be obtained with spirometry, including assessment of small airway function even in young children, using validated techniques such as the multiple breath washout test.[48]
7. An ultrasound examination of the pancreas can show atrophy or cystic changes in many patients with CF. Tests for abnormal glucose tolerance may also demonstrate CF pancreatic involvement.

## Transepithelial Potential Difference Measurements

In rare instances where the diagnosis of CF remains unclear or the evidence is equivocal, additional tests of CFTR function can be utilized. Patients with CF demonstrate defective chloride secretion and sodium hyperabsorption, and nasal potential difference (PD) measures the voltage created by chloride and sodium as they move across the epithelium. Nasal PD can be measured in the mucosa or the inferior turbinates by placing an exploring electrode on the respiratory epithelium and a reference electrode into the subcutaneous tissue of the forearm or an area of abraded skin. Baseline PD is more negative in patients with CF. Diagnostic accuracy is assured by documenting a bioelectric profile of change to the basal reading in the presence of amiloride application (becoming less negative in CF) with the addition of a chloride-free solution and isoproterenol (little or no response in CF; Fig. 50.1).[49,50] Results are influenced by recent viral infections, the presence of rhinitis, the precise anatomic localization of the measuring catheter, as well as polyps and the genotype. The test requires precise perfusion rates and duration of the chloride-free solution and the addition of isoprenaline. Not infrequently, atypical forms of CF with borderline sweat chloride levels produce a nasal PD that is also equivocal.[11,51] PD measurements are difficult to perform, especially in young children, and the technique is generally confined to specialist centers.[52,53] A video featured on the following website demonstrates the technique: http://www.rbht.nhs.uk/patients/condition/cystic-fibrosis/patient-information/films/#NPD.

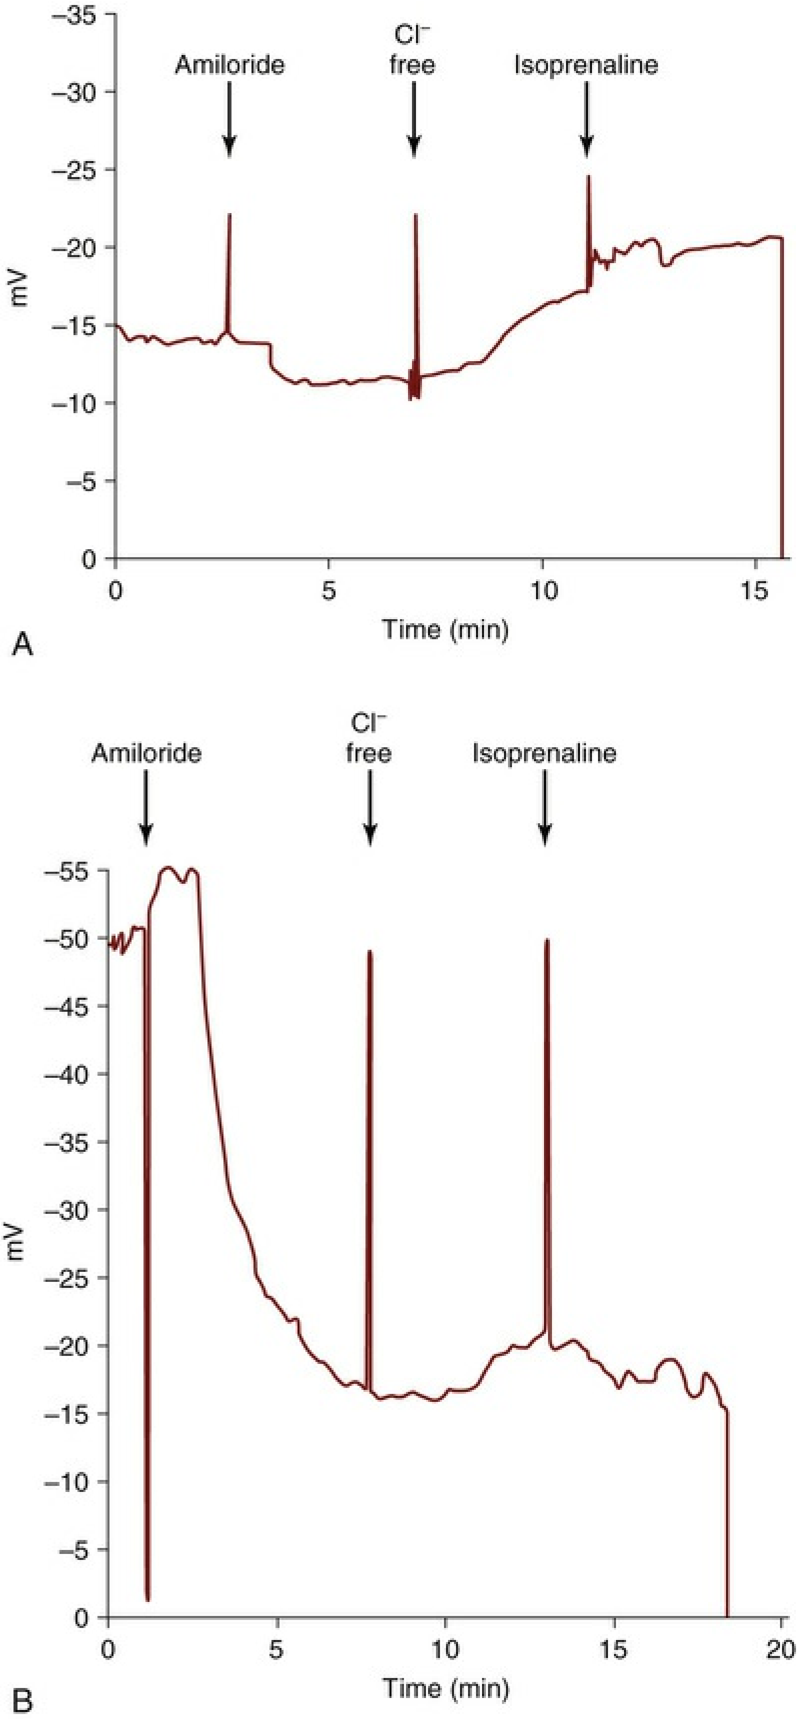

**FIG. 50.1** Nasal potential difference (PD) in a normal subject (A) and a cystic fibrosis patient (B), illustrating the difference in baseline PD, response to perfusion

with amiloride, followed by the addition of a chloride-free solution and then isoproterenol. Note that the spikes on the trace associated with the perfusion of solutions are artefactual and do not represent mucosal voltage changes. (With thanks to Dr. N. Simmonds for the trace.)

Alternatively to NPD and independent of the patient's age, intestinal current measurements can be done on rectal mucosal biopsy specimens ex vivo in an Ussing chamber.[54] This technique is not yet widely available and limited to a few centers.[55,56]

# Antenatal Testing for Cystic Fibrosis

Parents with an increased risk of having a child with CF, either because their own carrier status is known or because they already have an affected child, may request antenatal testing. The diagnosis can be confirmed or excluded, with a high degree of accuracy by direct mutation analysis performed on fetal cells obtained by chorionic villus sampling (10 weeks gestation) or cultured amniotic fluid cells (15–18 weeks gestation).

Preimplantation diagnosis is an alternative for at-risk couples. After in vitro fertilization, a cleavage-stage biopsy is carried out on day 2 or 3, and normal or carrier embryos are then transferred to establish pregnancy. Further postnatal confirmation is still recommended.

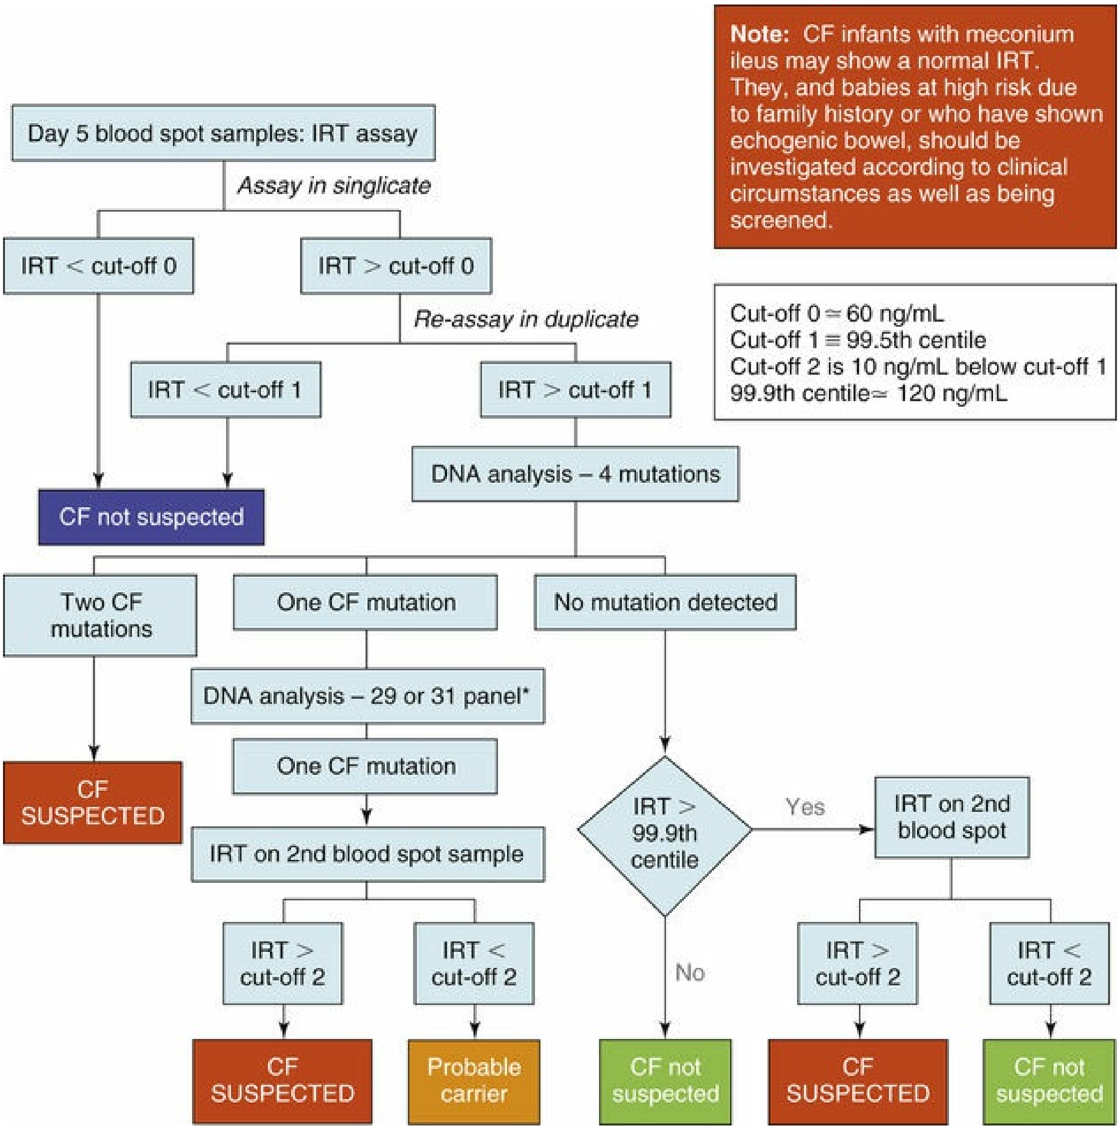
Occasionally, routine fetal anomaly scans may detect a suspicion for meconium ileus by abnormal bowel echogenicity or evidence of perforation. Although such findings are usually discovered too late into the second trimester to enable decisions on the fate of the pregnancy, a positive scan will help provide optimal facilities for the delivery and subsequent medical and surgical care. Hyperechoic bowel often occurs as a benign variant and is distinguished by spontaneous resolution, usually before the third trimester.[57]

# Neonatal Screening for Cystic

## Fibrosis

Although CF is not an ideal condition for a newborn screening program, as there is no highly specific or sensitive biomarker and there is no cure at this stage, the ability to identify CF in infants as early and accurately as possible has advantages that outweigh any potential disadvantages.[4,58,59] Over the last decade, newborn screening for CF has been widely adopted by many regions and countries and is now emerging as the commonest route to the diagnosis of CF, sharply altering the traditional diagnostic paradigm of symptom-led investigations described previously for the pediatrician. A range of screening algorithms has been developed, often to suit local resources and conditions.[31,60,61]

The first step of CF neonatal screening is usually based on the immunoreactive trypsin assay (IRT), which is relatively inexpensive to perform on the newborn heel prick sample (Guthrie test).[62] Increased IRT concentrations can be raised transiently in healthy newborns, but in newborns with CF IRT remains raised for weeks to months in both pancreatic sufficient and insufficient CF individuals. A repeat IRT 2 weeks after birth further improves the specificity of the screening algorithm.[63] Infants with raised or persistently raised IRT above a locally devised cutoff point proceed to further testing. This may consist of a panel of common CFTR mutations for the region performed on the same blood sample or a sweat test.[64,65] An example of the algorithm currently adopted by the United Kingdom is illustrated in Fig. 50.2.



Note: CF infants with meconium ileus may show a normal IRT. They, and babies at high risk due to family history or who have shown echogenic bowel, should be investigated according to clinical circumstances as well as being screened.
Day 5 blood spot samples: IRT assay
Assay in singlicate
IRT < cut-off 0
IRT > cut-off 0
Re-assay in duplicate
Cut-off 0 ≃ 60 ng/mL
Cut-off 1 ≡ 99.5th centile
Cut-off 2 is 10 ng/mL below cut-off 1
99.9th centile ≃ 120 ng/mL
IRT < cut-off 1
IRT > cut-off 1
DNA analysis – 4 mutations
CF not suspected
Two CF mutations
One CF mutation
No mutation detected
DNA analysis – 29 or 31 panel*
One CF mutation
CF SUSPECTED
IRT on 2nd blood spot sample
IRT > 99.9th centile
Yes
IRT on 2nd blood spot
No
IRT > cut-off 2
IRT < cut-off 2
IRT > cut-off 2
IRT < cut-off 2
CF SUSPECTED
Probable carrier
CF not suspected
CF SUSPECTED
CF not suspected

**FIG. 50.2** An example of a newborn screening algorithm using an IRT/IRT/DNA protocol. *CF,* Cystic fibrosis. *, In some areas this mutation analysis has been extended to include 50 CFTR mutations.

Screened babies may have early manifestations of pulmonary or gastrointestinal disease at the time of diagnosis, but may also be completely asymptomatic, even though they have two disease-causing mutations and a positive or intermediate sweat test. CF teams have had to acquire special skills in conveying information to the families of these seemingly well children.[66]

The CF screening program is primarily designed to pick up all cases of classical CF in newborns who have two disease-causing mutations and a positive sweat test who will benefit from early therapy, and to exclude healthy carriers. However, all newborn screening programs will also identify infants with an equivocal diagnosis where the screening results are neither clearly diagnostic nor normal. This has led to some confusion about this group—both in terms of nomenclature and subsequent clinical follow-up and management. For example, infants identified with hypertrypsinogenemia on NBS may have sweat chloride values less than 60 mmol/L (or even normal levels of <30 mmol/L) and up to two CFTR mutations, at least one of which is not clearly categorized as a "CF-causing mutation."[6,67] These infants do not fulfill all the diagnostic criteria for CF, are pancreatic sufficient, and have no or nonspecific clinical symptoms at the time of presentation to the clinicians. There has been significant debate on what to call such infants who do not have a disease and how to monitor them longer term for the emergence (if ever) of end organ changes that require intervention and control. The term CFTR-related metabolic syndrome (CRMS) has been proposed to describe these atypical cases in the United States—in an attempt to provide a label rather than a diagnosis but satisfy the need for funding to provide care.[6] Consensus documents outline possible management protocols. A collaborative European effort preferred the term "Cystic Fibrosis Screen Positive, Inconclusive Diagnosis" (CFSPID), which is used in most other parts of the world to describe this group of children and included a suggested follow-up plan.[5,69] The natural history of these children with CRMS/CFSPID is unknown. They may grow up to become adults who, in the prescreening era, would have been diagnosed with "CFTR–Related Disorders"—presenting with predominantly single-organ disease such as male infertility, sinusitis, pancreatitis, or allergic bronchopulmonary aspergillosis (ABPA). Equally they may enjoy trouble-free lives and never develop a disease at all or potentially emerge over time into a more classical CF phenotype.[70,71] Pediatric teams, with expertise in CF and its various clinical presentations, will need to develop follow-up plans to monitor these infants through their childhood so that treatable symptoms are not missed but unnecessarily burdensome treatments are spared.

## The Phenotypic Spectrum of Cystic

# Fibrosis—Influencing Factors

Although two disease causing CFTR mutations are likely to be associated with both a positive sweat test and the presence of disease manifestations in the lung, pancreas, and other organs, the road from genotype to phenotype is not easily predictable. As described in Chapter 49, mutations can be categorized as mild or severe, but the spectrum of phenotype is broad, even for a given CFTR mutation.[39,72] Different organs appear to have different thresholds for CFTR functioning. The vas deferens, for example, requires a relatively higher level of functioning CFTR and appears to be particularly sensitive.

There are four major contributing factors that influence the path from genotype to end-organ involvement and an individual's eventual phenotype[7,73]:

1. The severity of the individual CFTR mutations: “Mild” mutations may cause milder phenotypic effects, but when there is a mixture of mild and severe mutations, the final impact is less predictable. Similarly, coexistent polymorphisms hitchhiking within the CFTR gene may influence the final protein product—such as the polythymidine run (5T/7T), in conjunction with the R117H mutation.
2. Modifying genes: Genes other than CFTR lying elsewhere in the genome can have significant impact on the CFTR protein's clinical influence. These genes and their protein products can correct or exacerbate influencing pathological processes such as the biochemistry of the cell surface liquid, the innate and acquired immunity of the lungs, and may even influence the predisposition to meconium ileus.[74] Each individual with CF has an orchestra of modifying genes and proteins unique to themselves and influential in their clinical outcome in concert with their CFTR genotype.[75,76]
3. Environmental factors: The environment in which a patient with CF lives and grows has central bearing on the outcome of their disease. Poor access to treatment or nonadherence to therapy, social circumstances and diet, exposure to

infections such as pseudomonas, or viral infections in infancy can produce a sustained negative influence on the clinical course.

4. The passage of time is an important influence on outcome. CF is not necessarily an all-or-nothing disease. A clinical phenotype can emerge with time, for example, in those children initially designated as CRMS/CFSPID. Effective therapies and adherence to treatment can help stall the disease progression. Patients with documented pancreatic sufficiency in childhood can become pancreatic insufficient later in life. Some but not all patients with CF may, over time, develop diabetes, liver disease, and osteoporosis.

## Cystic Fibrosis Phenotypes

While CFTR dysfunction clearly causes a clinical spectrum of disease, three phenotypes can be distinguished:

### Classical CF

Most children with classical CF in current times are likely to be picked up through newborn screening programs and confirmed by the finding of two CF-causing mutations and a positive sweat test. They may be clinically well at the time of detection through the CF screening program but are highly likely to develop CF symptoms that require early intervention. Some children will be missed through screening, but no racial group is exempt from the disorder, and children of ethnic minorities or mixed heritage are at greatest risk of a delayed or missed diagnosis.[77] The clinical features of recurrent chest infections, malabsorption with pancreatic insufficiency in the majority (but not all), salt-losing syndromes, or infants presenting with meconium ileus or rectal prolapse require investigation. Appropriate therapy should be introduced without delay.

### CFTR-Related Disorders

The terms “CFTR-related disorders” or “atypical CF” or “nonclassic

CF" or "delayed CF" have all been used to describe individuals—often with single organ disease, and often picked up later in life—who have symptoms and signs reminiscent of those found in CF, but in whom the full diagnostic criteria are not met.[78–80] Sweat testing can be normal, intermediate, or positive, and mutation analysis may reveal one or two CFTR mutations whose clinical significance is uncertain. Examples of such conditions are listed in Box 50.5. Most of these individuals are currently detected in later childhood or as adults. Caregivers have recognized that it is inappropriate to label individuals with these atypical forms as having classic CF.[81] Both the diagnostic labeling and management needs to be tailored to the patient's individual phenotype and requirements.[67] The introduction of arduous therapies aimed at the patient with classical CF may not be appropriate or beneficial. The negative connotations of a CF label can be avoided with a more considered approach to diagnostic categorization.

**Box 50.5**

### Conditions That May Be Associated With an Increased Incidence of Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) Mutations and Partial Evidence for CFTR Dysfunction But Insufficient Evidence to Fulfill a Cystic Fibrosis Diagnosis

Pancreatitis—acute or recurrent
Disseminated bronchiectasis
Isolated obstructive azoospermia
Allergic bronchopulmonary aspergillosis
Diffuse panbronchiolitis
Sclerosing cholangitis
Rhinosinusitis
Heat exhaustion

The concept of classical and atypical forms has been useful in countering the "all-or-nothing" approach to the diagnosis of CF. Equally, however, it should be recognized that careful monitoring and timely management are crucial for all affected children—even those with atypical forms. Terms such as "atypical" or "mild" should not lead to complacency in care and follow-up.

It is likely that some of the children currently detected through newborn screening and labeled as CRMS/CFSPID (described later) may emerge over time to develop single organ disease and move into the CFTR-related diagnostic category.[70,71]

## CFSPID/CRMS

As discussed previously, the newborn screening program can detect NBS infants with hypertrypsinogenemia subsequently identified with one or two CFTR mutations of uncertain clinical significance and a normal or equivocal sweat test. As such, they do not fit the criteria for a CF diagnosis. The term "cystic fibrosis screen positive, inconclusive diagnosis" (CFSPID) was considered preferable for these children in a European consensus study. Like the acronym, CRMS, it is a label, not a diagnosis. These children do not have clinical symptoms, and there is no evidence for end organ CF disease. Before the advent of widespread screening programs, this scenario was rarely encountered and considered a form of genetic "pre-CF."[83] Currently this group can comprise between 10%–40% of the CF screen–positive infants—and even more depending on the local cutoff levels for IRT.[84,85] There is the potential that clinical features may emerge with time, but there is insufficient evidence to label these asymptomatic infants as CF or even atypical CF. Most clinicians would advise a program of careful surveillance, including repeating the sweat test during the first 2 years of life.[69] The role of prophylactic therapy such as physiotherapy or antibiotics is unclear, and the need for regular surveillance respiratory cultures is debated. The natural history for this group of children is likely to emerge with greater clarity over the next decade.[8,86] The decision to reclassify children designated as CRMS/CFSPID will need to take into account functional assessment of CFTR (sweat chloride, nasal PD), CFTR genetic analysis, and evidence for organ disease, as assessed by an experienced CF team.

# Pulmonary Disease in Cystic Fibrosis

*Peter Michelson MD, MS, Albert Faro MD, Thomas Ferkol MD*

## Epidemiology

While present in all races and ethnicities, cystic fibrosis (CF) is the most common, life-shortening inherited disease of Caucasians. An autosomal recessive defect, occurring in approximately 1 in 3500 live births based on data from neonatal screening, the life expectancy of a child born with CF has gradually improved and now exceeds 40 years in the United States.[1] The predominant morbidity and mortality from CF continues to result from progressive pulmonary involvement. The CF lung is susceptible to infection; endobronchial infection induces an intense inflammatory response that leads to bronchiectasis and eventually respiratory failure, thus shortening the life of the patient. In this chapter, we will build on earlier sections and relate the pulmonary manifestations and complications of CF lung disease to its pathophysiology, and describe current and emerging therapies to address this progressive lung disease.

## Etiology and Pathogenesis

CF is caused by defects in the CF transmembrane conductance regulator (CFTR), a cyclic adenosine monophosphate (cAMP)-

regulated chloride channel expressed on the surface of airway epithelial cells and the serous cells of the submucosal glands (discussed in more detail in Chapter 49).[2] CFTR is functionally linked to other apical chloride channels, such as the calcium-dependent chloride channels (ClCa), and the epithelial sodium channel (ENaC), which reabsorbs sodium in the airways (Fig. 51.1). Aberrant expression or function of CFTR in the airway leads not only to reduced chloride conductance but also upregulation of ENaC activity. Failure of chloride secretion and sodium hyperabsorption result in dehydration of the airway surface. The reduced airway surface liquid and desiccated secretions obstruct the airways and reduce mucociliary clearance, permitting bacterial infection to become established and allowing the inflammatory response to be amplified.[3–5] The mucus secreted by submucosal glands in the CF airway is also abnormal, possibly related to altered CFTR anion transport, and hinders bacterial clearance.[6] Gaps in innate airway defenses contribute to bacterial persistence and chronic infection in the CF airway. Altered bicarbonate secretion in the CF airway impairs the activity of airway epithelial antimicrobial proteins and thus interferes with innate airway defenses resulting in chronic infection (Fig. 51.2).[6–8]

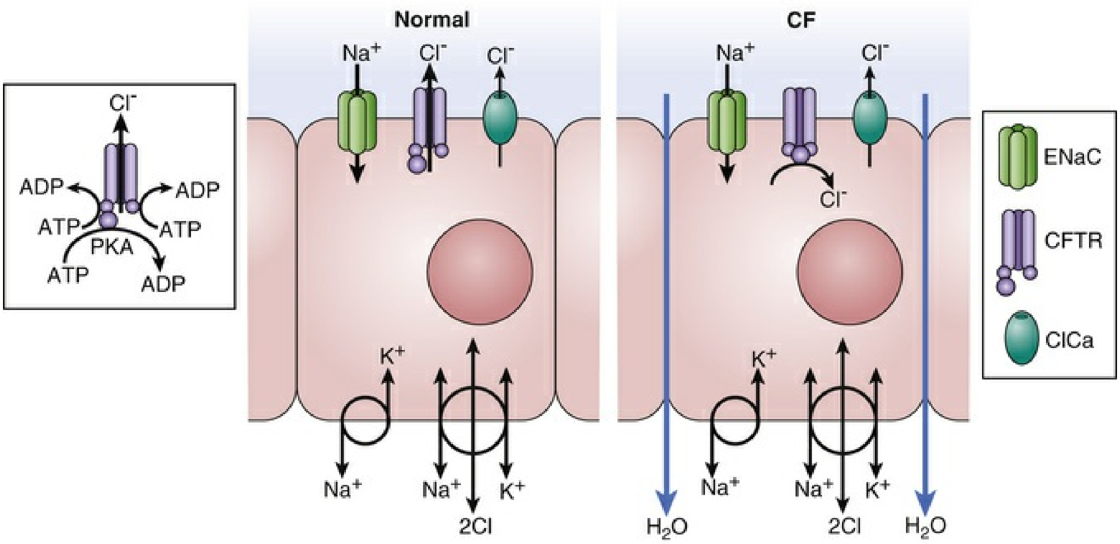

**FIG. 51.1** Schematic diagram depicting cystic fibrosis *(CF)* epithelial channel defects, characterized by impaired chloride secretion, massive sodium absorption, and movement of water through the

epithelium, leading to a dehydrated airway surface. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *CFTR,* cystic fibrosis transmembrane conductance regulator; *ClCa,* alternative chloride channel; *ENaC,* epithelium sodium channel; *PKA*, protein kinase A.

The decreased periciliary fluid volume also concentrates inflammatory mediators at the immediate epithelial surface. *CFTR,* Cystic fibrosis transmembrane conductance regulator; *ClCa,* alternative chloride channel; *ENaC,* epithelium sodium channel. (Modified from Pittman JE, Ferkol TW. The evolution of cystic fibrosis care. *Chest.* 2015;148:533-542.).

Respiratory infections are not a consequence of altered or abnormal pulmonary development. The lungs of neonates with CF appear histologically normal with the exception of plugging and distension of submucosal gland ducts. Bacterial cultures of respiratory secretions from infants often fail to yield a specific pathogen. Early in life, the airways are not chronically infected, although various bacteria may be found intermittently. As intrabronchial mucus stasis evolves, the respiratory tract becomes persistently infected with common patterns of bacterial species (Fig.

51.3). Bacterial infection is highly localized to the airway.[9–12]

(Modified from Pittman JE, Cutting G, Davis SD, Ferkol T, Boucher R. Cystic fibrosis: NHLBI Workshop on the Primary Prevention of Chronic Lung Diseases. *Ann Am Thorac Soc.* 2014;11(suppl 3):S161-S168.).

Initially, *Staphylococcus aureus* and *Haemophilus influenzae* are isolated from patients with CF. *S. aureus* is often found in the respiratory tract of infants and young children with CF and the prevalence of methicillin-resistant *S. aureus* strains has greatly increased.[13] There is mounting evidence that methicillin-resistant *S. aureus* contributes to pulmonary deterioration and poorer survival.[14,15] The significance of *H. influenzae* in the progression of CF lung disease is uncertain, although it is a recognized and often treated pathogen in other forms of bronchiectasis.[9,16]

*Pseudomonas aeruginosa* emerges as the predominant organism over time but the percentage of children with chronic lung infection with *P. aeruginosa* has declined, with less than 50% of patients transitioning to adult care centers testing positive for *P. aeruginosa.*[1] Early *P. aeruginosa* isolates have planktonic, motile, nonmucoid phenotypes. Most patients eventually become chronically infected with mucoid *P. aeruginosa* that survives in the lung as biofilms, and these anaerobic, sessile communities of bacteria contribute to antibacterial resistance in the CF airway.[9,17,18] Approximately 70% of CF adults in the United States are chronically infected with mucoid *P. aeruginosa*[1] and the isolation of mucoid strains from the lungs of a patient is characteristic but not pathognomonic for CF.[19] Isolation of mucoid strains of *P. aeruginosa* from the lungs of a patient is associated with a poorer prognosis. Encouragingly, studies have reported that persistent infection with *P. aeruginosa* can be delayed or avoided with antibiotic treatment, which may lead to slower decline in pulmonary function.[20–22]

Antibiotic-resistant strains of *P. aeruginosa* are found increasingly in CF respiratory secretions. Other resistant, gram-negative bacteria, *Stenotrophomonas maltophilia* and *Achromobacter xylosoxidans,* are opportunistic organisms that may appear later in life; recent cohort data suggest some impact on disease progression with *Stenotrophomonas,* but further analysis is warranted.[23–25] Alternatively, *Burkholderia cepacia complex* can have profound effects on the clinical course of the disease and be associated with rapidly progressive necrotizing pneumonia and greater mortality.[26,27] The prevalence of *B. cepacia* complex varies markedly between care centers with a nationwide prevalence of about 2%.[1] Most *B. cepacia* complex infections are caused by genomovar II *(B. multivorans)* and genomovar III *(B. cenocepacia).* These organisms are transmissible, and infection control policies are critical to limiting exposure and spread. Epidemic infections have been linked to *B. cenocepacia,* but other genomovars have been associated with severe disease.[28,29] To prevent bacterial transmission between CF patients, infection control guidelines have been developed and applied to patients in both clinical settings and during social activities.[30]

Invasive fungal infections are rare. Nontuberculous mycobacteria, typically *M. avium-intracellulare* complex or *M. abscessus,* can infect the CF lung. About 13% of patients in the United States harbor nontuberculous mycobacteria in their lungs.[31]

Therefore CF patients should be screened at least annually for mycobacterial colonization.

In patients with respiratory symptoms refractory to antibiotic therapy, viral infections should be considered. Indeed, there is evidence indicating that viruses play a significant role in the pathogenesis of pulmonary exacerbations and are associated with progressive clinical deterioration.[32] Respiratory viruses have the potential for injuring or altering the airway and can induce secretion of inflammatory mediators from respiratory epithelium. Moreover, viral infections result in a damaged epithelial barrier, leading to acquired ciliary dyskinesis, disruption of cell-cell connections, and cell death.[33] A breach in the airway epithelium potentially allows pathogens to reach the basolateral surface, provoking a greater inflammatory response.[34] Viral infections can affect airway surface fluid levels in CF epithelial cell cultures, which could further impair mucociliary clearance.[35] In particular, influenza can complicate CF disease, but immunization and chemoprophylaxis have lessened its clinical impact.

Although pulmonary infection contributes to the morbidity of patients with CF, an intense host inflammatory response hastens the progressive, suppurative pulmonary disease. Inflammation in the CF lung is primarily contained in the airway lumen, while the alveolar space is relatively spared (Fig. 51.4). The airway is filled with mucopurulent secretions. Large numbers of neutrophils are found in the airway, even in children with mild disease.[36,37] Bronchoalveolar lavage (BAL) fluid from CF patients has remarkably high concentrations of proinflammatory mediators.[38,39] Infection and local mediators stimulate epithelial cell secretion of IL-8, a potent neutrophil chemoattractant and activator that perpetuates airway inflammation. Complement-derived chemoattractants and leukotriene $B_4$ also contribute to neutrophil influx.[40,41] Both IL-1β and TNF-$\alpha$ are macrophage-derived cytokines that contribute to the local inflammatory response in the CF airway by mediating neutrophil chemoattraction and degranulation. IL-17 pathways have also been identified to contribute to the proinflammatory gene expression in the airway and are especially involved in established CF lung disease.[42,43]

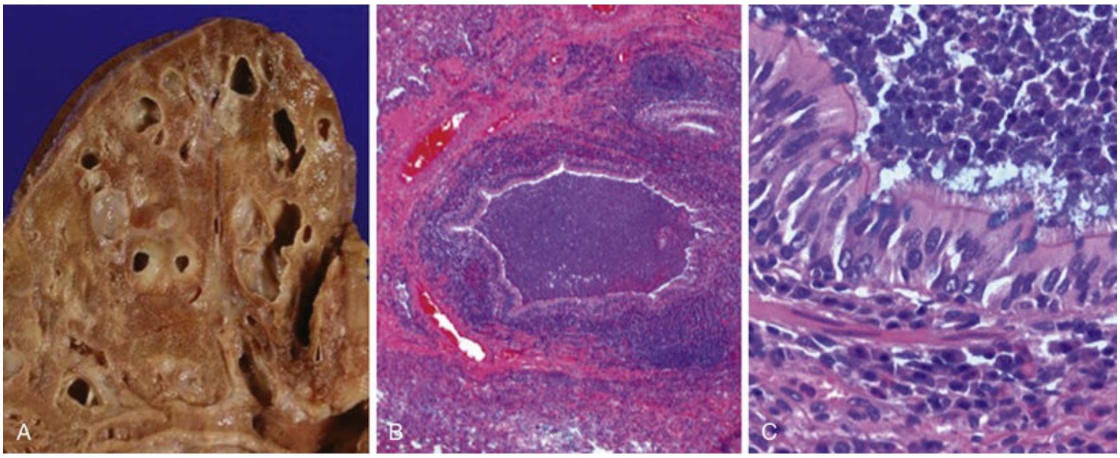

**FIG. 51.4** Pathology of cystic fibrosis lung disease. (A) Photograph of lung explant from an adolescent cystic fibrosis (CF) patient showing bronchiectatic changes and mucus plugging, primarily involving the upper lobe (image generously provided by Carlos Milla, MD, Stanford University). (B and C) Photomicrographs of a section of CF lung explant (40× and 400×, magnification), demonstrating intense endobronchial and peribronchial inflammation with plugging of airways by exudate, degenerating neutrophils, bacteria, and mucus.

Inflammation in the CF lung is primarily driven by local stimuli, mediators, and chemoattractants and is not a local effect of a systemic inflammatory reaction. Systemic indicators of inflammation are often normal or only modestly increased, even during acute illnesses. Several lines of evidence suggest that airway inflammation in CF may be excessive to the threat posed by bacteria, possibly mediated through dysregulation of the transcription factor nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) or other signal transduction molecules.[44–49] Although not a universal finding, infants and children with CF have high levels of proinflammatory cytokines and neutrophils in BAL fluid, even in the absence of detectable infection.[10,11] It is possible that inflammation may occur independent of infection or that a relatively minor infection may induce a robust inflammatory reaction in the CF lung that does not subside. However, not all experimental models and clinical studies have demonstrated an exaggerated inflammatory response in the CF airway,[50–52] and this phenomenon may be related to reduced apical surface fluid volume.[53]

The inflammatory response in the CF airways is characterized by a massive influx of neutrophils across the respiratory epithelium, even in individuals with mild pulmonary involvement. The phagocytic system affords protection against bacterial invasion, and neutrophil-derived proteases, such as neutrophil elastase, are released during phagocytosis and neutrophil death. These proteases participate in the intralysosomal degradation of engulfed bacteria and with disease progression the protease burden in the CF airway overwhelms existing antiprotease defenses.[37,54,55] Neutrophil elastase plays several roles in the pathogenesis of CF lung disease. It digests diverse substrates, including structural proteins, which weakens the airway and results in bronchiectasis and bronchomalacia. Uninhibited neutrophil elastase can enhance the inflammatory response in the bronchi[56] and, paradoxically, interfere with nonspecific airway defenses.[57,58]

As disease progresses, the airway lumen is filled with neutrophil exudates, acute and chronic inflammation, and bacteria. Mononuclear cell infiltration of the submucosa, goblet cell hyperplasia, and submucosal gland dilatation are also features of the CF airway. Respiratory cilia are normal or have nonspecific changes secondary to epithelial injury. Bronchiectasis is the predominant pathological feature, more severe in the upper lobes. Despite high bacterial concentrations in the CF lung, bacteremia and sepsis are rare. Tissue invasion is uncommon, and usually associated with particular organisms, such as *B. cepacia* complex.[29] Segmental hyperinflation or atelectasis results from airway obstruction. Lung overinflation, postinflammatory blebs, and bronchiectatic cystic lesions increase susceptibility to pneumothorax. Over time, bronchial arteries become hypertrophied and can cause pulmonary hemorrhage. Chronic alveolar hypoxia and inflammatory changes contribute to pulmonary hypertension and cor pulmonale.[59]

# Clinical Features

## Symptoms and Physical Findings

The onset and progression of clinical manifestations of CF lung disease is highly variable and detecting the presence of disease in infants and children can be challenging. Although it is unusual for neonates to manifest respiratory symptoms, the work of the Australian Respiratory Early Surveillance Team for Cystic Fibrosis (AREST CF) has shown that relatively well children have evidence of CF lung disease during the first few months of life.[60,61] Viral illnesses in older infants can precipitate tachypnea, wheezing, and cough, but early colonization with lower airway pathogens, specifically *S. aureus* and *P. aeruginosa*, may be associated with pulmonary inflammation, early-onset bronchiectasis, and an associated decline in lung function.[62]

Most children will present with cough as their primary symptom, which becomes increasingly productive. Mucociliary clearance is impaired throughout the conducting airways, and the CF patient depends on cough to mobilize purulent endobronchial secretions and reduce bacterial burden. As the lung disease progresses, CF patients can experience exercise intolerance, dyspnea, and shortness of breath.[63] Typically, bronchiectasis begins in the upper lobes in CF patients and then progresses to involve the whole lung (Fig. 51.5).[64] The treatment of bronchiectasis is the treatment for the CF lung disease. Lobar resection is seldom indicated but may be considered in instances of severe hemoptysis or bronchiectasis that are not responsive to conservative management.[65,66]

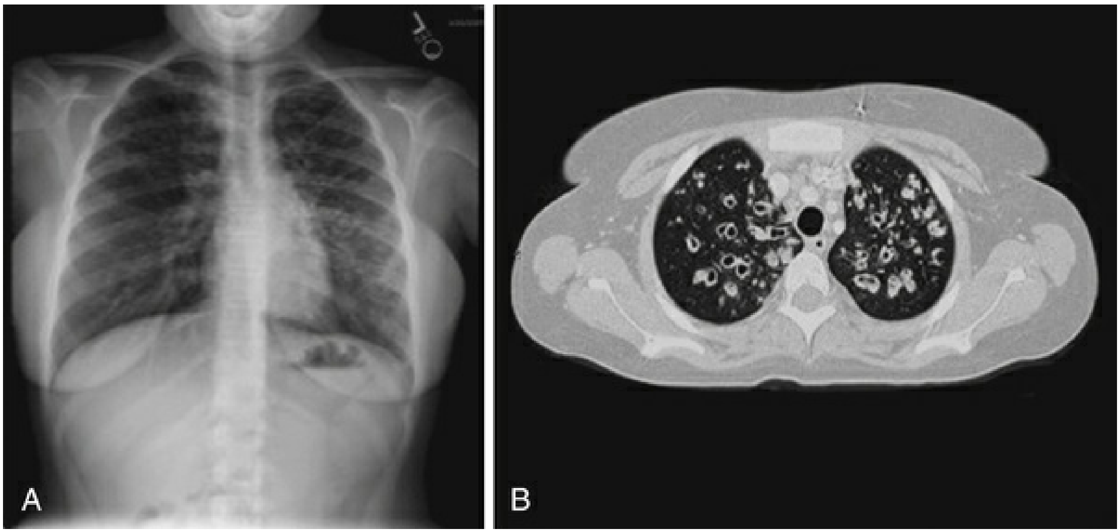

**FIG. 51.5** Chest imaging of a cystic fibrosis patient.

Standard posteroanterior radiograph (A) and high-resolution computerized tomography (B) of the chest show lung overinflation, bronchiectasis, and airway wall thickening.

Atelectasis often coexists with bronchiectasis because of the accumulation of purulent secretions and airway obstruction. Atelectasis also generates negative intrapleural pressure and dilates the associated bronchus that has been already weakened by the lytic enzymes released from neutrophils in the purulent material in the airway. Typically, treatment for atelectasis involves airway clearance techniques, inhaled recombinant DNAse (dornase alfa), or other mucolytic agents, plus antimicrobials.

Altered balance between airway pathogens and local host defenses leads to acute changes in respiratory signs and symptoms; this phenomenon is termed a *pulmonary exacerbation*.[67] Clinically, a pulmonary exacerbation is manifested as increased respiratory symptoms such as cough, dyspnea, and sputum production, often accompanied by systemic symptoms such as fatigue, anorexia, and weight loss. Pulmonary function values usually decrease during exacerbations, and a therapeutic goal is to restore the best baseline of pulmonary function, regardless of the patient's symptoms. Exacerbations are treated with aggressive airway clearance techniques and antibiotic therapy based on bacterial isolates from sputum or oropharyngeal cultures.[67,68]

CF patients have chronic upper respiratory tract involvement, clinically manifested as nasal congestion and rhinorrhea. Pansinusitis is almost universally present in affected individuals. If upper airway symptoms worsen, systemic antibiotic therapy may be indicated. The percentage of CF patients who have features consistent with clinical sinusitis varies widely.[69,70] Bacteria isolated from the paranasal sinuses parallel those found in the lower respiratory tract, although distinct strains may colonize different anatomic sites in the CF airway.[71–73] Occurring in 7%–56% of CF patients, nasal polyposis is a common complication leading to nasal obstruction and congestion, which can require surgical intervention.[74] Surgical management usually results in symptomatic improvement, but sinusitis and polyps often recur.[75]

Digital clubbing is a sign of long-standing pulmonary involvement and eventually develops in virtually all CF patients. Hypertrophic pulmonary osteoarthropathy, a syndrome characterized with clubbing, long bone periostitis, and synovitis that usually flares during acute pulmonary exacerbations, has been described infrequently in CF patients and is usually associated with more advanced lung disease.[76]

As airway disease progresses, there is an increased likelihood of respiratory complications, including hemoptysis and pneumothorax. Pneumothorax is a late and worrisome complication of CF lung disease resulting from severe obstructive airways disease and/or the rupture of overexpanded apical blebs. Approximately 3% of CF patients will experience pneumothorax during their lifetime, and the average annual incidence of pneumothorax is 0.6%.[77] Pneumothoraces are usually associated with more severe disease (75% occur in patients with a forced expiratory volume in one second [$FEV_1$] of less than 40%)[78,79] and can be associated with fatalities. Although small pneumothoraces can be treated conservatively, evacuation of intrapleural air is often necessary to reexpand the lung. With recurrence rates ranging 50%–90%,[80] chemical or mechanical pleurodesis may be indicated, depending on the clinical scenario; even with pleurodesis, the risk for recurrent pneumothorax remains high.[79] Whereas pleurodesis was previously considered an absolute contraindication for lung transplant referral, that is no longer universally applied.[81]

Hemoptysis is common in older CF patients, particularly during pulmonary exacerbations, and is usually treated with antibiotics and, depending on the volume, withholding airway clearance. As CF lung disease progresses, bronchial arteries or collateral vessels enlarge and may rupture into an inflamed airway, producing massive hemoptysis, defined as more than 240 mL in 24 hours. This is a medical emergency, and roughly 4% of all patients with CF will suffer massive hemoptysis in their life.[77] These episodes can be fatal. Although many episodes spontaneously remit, hemoptysis can be worsened by coagulopathy secondary to hypovitaminosis K or underlying CF liver disease. Although patients can be stabilized with intravenous vasopressin, selective bronchial artery embolization is the definitive treatment.[82] Recurrent hemoptysis does occur, and repeated embolization may be indicated.

Airway hyperreactivity is often diagnosed in patients with CF, as evidenced by routine treatment with inhaled albuterol and corticosteroids. Roughly half of CF children and adults have a bronchodilator response, even if they do not have asthmalike symptoms, and the degree of airway hyperresponsiveness may change over time.[83,84] In different studies, airway hyperresponsiveness to exercise, histamine, or methacholine were found in 22%–54% of CF children.[85,86]

The defect in airway clearance associated with CF may also allow for endobronchial fungal growth and the development of allergic bronchopulmonary aspergillosis (ABPA).[87,88] ABPA is an inflammatory complication, clinically manifested by wheezing and cough refractory to standard therapies. Bronchiectasis with mucus impaction and atelectasis should also prompt consideration of ABPA.[89,90] ABPA is an intense immunologic response to surface colonization with the fungus *Aspergillus fumigatus,* which is characterized by (1) clinical deterioration that is not explained by other etiologies, (2) elevated serum quantitative immunoglobulin (Ig) E concentrations (>500 IU/mL), (3) positive skin prick test to *Aspergillus fumigatus* or elevated *in vitro Aspergillus*-specific IgE levels, and (4) *Aspergillus*-specific IgG levels or precipitins. Fulfilling these diagnostic criteria complicates the diagnosis and results in varying prevalence rates. Features that should raise concerns for the diagnosis include high-resolution computed tomography (HRCT) findings of mucus impaction, central bronchiectasis, tree-in-bud opacities, and centrilobular nodules.[88,91] Serum quantitative IgE concentrations should be measured annually to monitor for this complication. Once the diagnosis is made, patients are treated with extended courses of high-dose corticosteroids. Antifungal therapy is a therapeutic option to reduce the antigen burden in the lung, but few studies have shown that this strategy reduces the duration of corticosteroid treatment or improves outcome.[92]

Cor pulmonale is a complication of hypoxemia that is most commonly seen in older patients with advanced disease. Aggressive treatment of the underlying lung disease is indicated in early pulmonary hypertension, combined with oxygen supplementation. With disease progression and volume overload, diuretics are indicated to treat the right-sided heart failure.[93] With more advanced disease, the presence of pulmonary hypertension significantly reduces life expectancy.[94]

## Imaging and Laboratory Studies

The United States Cystic Fibrosis Foundation (CFF) has established Clinical Practice Guidelines that outline standards for routine monitoring and intervention to slow progression of lung disease. Evaluations include regular radiologic examinations, pulmonary function testing, and microbiologic cultures of airway secretions. Clinical evaluations are also essential and include monitoring for weight loss, anorexia, exercise tolerance, and school attendance, which are indirect measures of pulmonary morbidity. Indeed, the child's nutritional health is relevant to pulmonary outcomes. Younger children who have maintained their body weight had better pulmonary function at age 6 years, showing the relationship between nutrition and lung disease.[95]

## Monitoring Lung Disease

Chest imaging studies are useful tools to assess disease progression. Standard chest radiographs are often normal early in life, but as lung disease evolves, hyperinflation, peribronchial thickening, mucus plugging, and atelectasis develop. The progressive bronchiectasis, characteristic of CF lung disease, is usually a later finding on plain chest films. HRCT of the chest is more sensitive and provides greater anatomic detail, showing abnormalities well before detection on plain radiographs or changes in pulmonary function. HRCT can be performed on infants and small children, and it may reveal unsuspected airway wall thickening, segmental overinflation, and early bronchiectasis.[61,96–98] Although scoring systems to measure the extent and progression of CF lung disease have been developed, there are still no consensus guidelines regarding the use of computerized tomography, and the long-term consequences of radiation exposure remain concerns.[99–101]

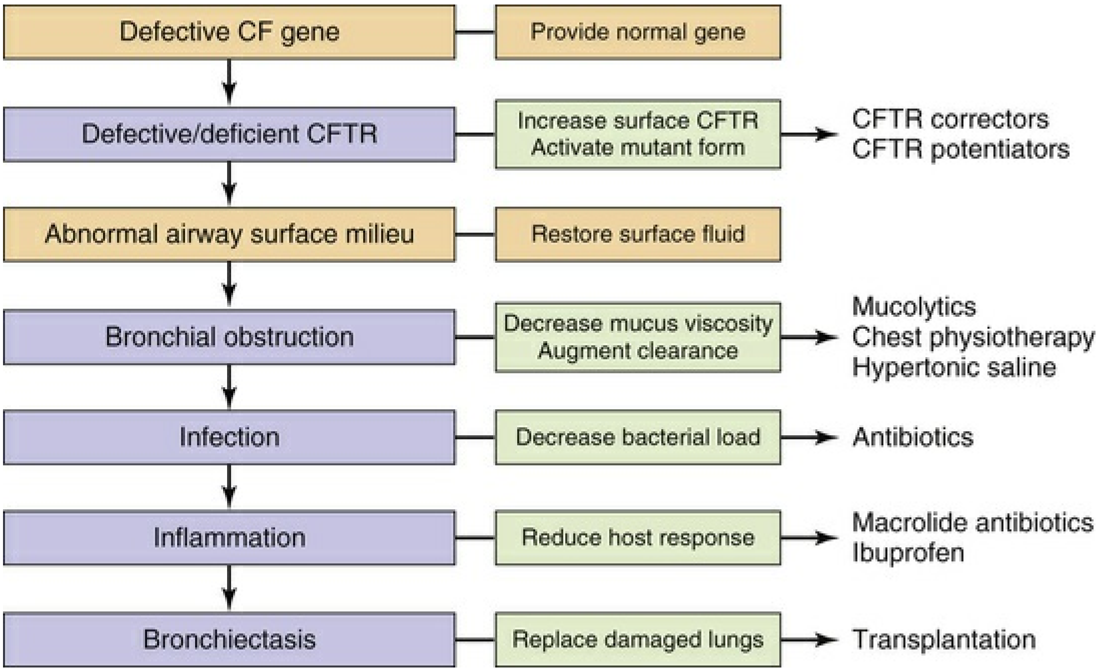
Pulmonary function testing is routinely used to assess lung disease in children and adolescents with CF. Spirometric measurements permit assessment of progression of airway disease and are routinely used to diagnose pulmonary exacerbations and response to antibiotic therapy. Most CF children are able to perform reproducible spirometric maneuvers by age 6 years. The $FEV_1$, or more accurately, the rate of $FEV_1$ decline, is a useful index of disease severity. Deteriorating $FEV_1$ is a key marker for disease progression.[102–104] Pulmonary function decline varies greatly between patients, but in this decade, the average annual reduction in $FEV_1$ is approximately 2% per year in the United States. Although first described more than 25 years ago, CF patients with a baseline $FEV_1$ 30% of predicted for age, still have a 2-year mortality rate of 50%.[102] Blood gas measurements are remarkably normal until late in the course of disease, but may reveal gas exchange abnormalities related to worsening ventilation-perfusion inequalities in patients with more advanced lung disease or clinical deterioration. Finally, infant pulmonary function testing can be a useful tool to assess infants and young children, but its value is limited by its ability to predict later disease severity. Recent testing in preschool children, including the multiple breath washout test or lung clearance index (LCI), has promise as an objective outcome measure in CF.[105]

Since progression of CF lung disease is inextricably linked to airway infection, regular comprehensive microbiological assessments of specimens from the lower respiratory tract, for example, sputum, are important.[9] Younger patients may not be able to expectorate, and in those cases, respiratory secretions can be collected using posttussive oropharyngeal swabs or BAL. Investigations have shown that negative oropharyngeal cultures may exclude lower airway infections, but a positive culture is not reliable to make the diagnosis of *P. aeruginosa* endobronchitis.[106] It is essential that respiratory cultures are processed and performed in laboratories with expertise in the handling of CF specimens and that recognize the difficulties in speciation of infecting pathogens. The CFF has established guidelines for handling and processing of respiratory tract specimens and supports reference laboratories for confirmatory identification of certain organisms such as *B. cepacia* complex.

Hypertonic saline has been used to induce sputum for lower airway sampling for both microbiological and inflammatory markers in older pediatric patients.[107] Cytokines, chemokines, oxidation species, and neutrophil products are elevated in the CF lung and may also be increased in the sputum and BAL fluid during exacerbations. However, such measures can have significant interpatient and intrapatient variability, even in those with seemingly stable lung disease. It is unclear whether these markers reflect disease progression, although the presence of detectable neutrophil elastase in lavage fluid early in life predicts development of bronchiectasis.[108] Inflammatory markers in the blood, such as peripheral leukocyte counts and C-reactive protein levels, have not been useful in the assessment of lung disease.

## Management and Treatment

Treatment for CF lung disease is evolving, incorporating the newer therapies developed over the last two decades.[63,109] Current management of CF incorporates antibiotics, inhaled mucolytics, vigorous airway clearance, nutritional support, antiinflammatory agents, and, increasingly, small molecule potentiators and correctors in an attempt to forestall progression (Fig. 51.6).[110–112] Indeed, early intervention and primary prevention of CF lung disease may be possible.[113]



Defective CF gene
Provide normal gene
Defective/deficient CFTR
Increase surface CFTR
Activate mutant form
CFTR correctors
CFTR potentiators
Abnormal airway surface milieu
Restore surface fluid
Bronchial obstruction
Decrease mucus viscosity
Augment clearance

## Airway Clearance

Effective airway clearance is a critical component of CF therapy.[114] To maintain lung health, physical removal of airway secretions is needed to not only relieve airway obstruction but also to reduce infection and airway inflammation.[115] Numerous airway clearance therapies (ACT) have been utilized and remain one of the most fundamental therapies for individuals with CF.[116] Additionally, novel agents aimed at restoring airway surface liquid and changing mucus viscosity have provided new opportunities to clear mucus and sustain normal lung function.[117]

There are many passive and active methods of ACT used in CF care. Active ACT includes positive expiratory pressure, active-cycle-of-breathing technique, and autogenic drainage.[116,118] No specific ACT has been definitively shown to be superior in changing long-term clinical outcomes, although this may be attributable to the challenges of performing randomized controlled trials in this area and the resultant paucity of data. An individual's choice should be based on age, experience, apparent effectiveness, and adherence.[63,119]

As an adjunct to airway clearance techniques, one must consider the benefit offered by aerobic exercise to mobilize secretions. In a systematic review of exercise for children with CF, both improved pulmonary function and aerobic fitness were demonstrated.[120] In addition to increased aerobic fitness, exercise programs may confer both short and long-term protection against pulmonary function decline.

Any discussion of ACT would be incomplete without discussing the advances in agents aimed at rehydrating secretions.[121] Reduced mucus viscosity and increased mucociliary clearance is achieved by improved airway surface hydration offered by these agents.[122,123] Hypertonic saline acts directly as an osmotic agent and may increase airway surface liquid volume. In older CF patients, hypertonic saline resulted in reduced frequency of pulmonary exacerbations and enhanced airway clearance.[124] A similar beneficial effect was not seen in children between 4 and 60 months of age.[125] However, in a small, pilot, single-center sub-study of young children, the lung clearance index (LCI) was significantly decreased in the group that received hypertonic saline.[105] As a result, a larger, multicenter investigation is ongoing. Working as a surface-acting osmotic agent, inhaled mannitol has been shown to improve lung function over 52 weeks in a placebo-controlled trial.[126] In addition, trials are underway to study the effect of ENaC inhibitors to rehydrate the CF airway. Finally, inhaled bronchodilators are often used before ACT to maintain airway patency and facilitate mucus removal.[127]

## Inhaled Mucolytics

Aerosolized mucolytics facilitate airway secretion clearance. The inspissated secretions in CF are predominately composed of pus with high concentrations of DNA from degraded neutrophils. Inhaled recombinant DNAse treats CF lung disease[128] by reducing sputum viscosity and increasing mucus clearance. Regular administration leads to improvement in lung function in some individuals with CF and is widely used. *N*-acetyl-L-cysteine is an alternative mucolytic agent, as it hydrolyzes disulfide bonds in mucins, and it has a long history of use in CF[129]; however, few data support its effectiveness other than as an airway irritant that induces cough.[130] Other mucolytics remain under investigation as potential therapeutic agents.[128]

## Antibiotic Therapy

During the past two decades, antibiotic use in CF care has evolved in both indications for usage and modes of delivery. Antibiotics continue to be utilized in the setting of acute infections and pulmonary exacerbations, but they are now also routinely used to eradicate organisms in otherwise asymptomatic young children or to reduce the bacterial burden in chronically infected patients.

CF patients acquire bacterial pathogens in an age-dependent manner that will chronically colonize their airways over time. Chronic infection with *P. aeruginosa* portends a poorer prognosis and, once established, is virtually impossible to eradicate.[9,18,19] However, studies treating initial acquisition of *P. aeruginosa* have shown that the organism can be eradicated with aggressive antibiotic therapy.[20,21,131] Although patients reacquired the organism later, the realization that early *P. aeruginosa* infection can be effectively eradicated led to a change in how antibiotics are prescribed in CF. No longer are antibiotics solely used to treat symptomatic disease; now they are used to treat early positive *P. aeruginosa* cultures, even in the absence of symptoms. Although effective in reducing reacquisition of *P. aeruginosa,* the impact of early eradication on later lung function remains obscure.[132] Potential confounders include the frequent use of antibiotics for pulmonary exacerbations and the need for longer follow-up of the two groups (those who achieved eradication and those who did not). In addition, there is insufficient evidence to support whether one antibiotic regimen is superior to another in achieving eradication.[22,133,134]

Although there is no consensus as to what defines a pulmonary exacerbation, most clinicians would agree that increase in cough, increase in sputum production, decline in lung function, shortness of breath, weight loss, and new adventitious sounds on auscultation warrant further investigation or therapy. Antibiotic treatment during an exacerbation, depending on the circumstance, may be delivered intravenously, orally, or by nebulization. The severity of the symptoms and the patient's available resources will assist the clinician in determining the appropriate course of therapy. Antibiotic therapy is typically guided by the findings of previous sputum or deep oropharyngeal culture and the susceptibility testing of the identified organisms. These cultures typically reflect the airway flora in older children and adolescents, but that may not be the case in infants.[106] BAL fluid cultures may be necessary to more accurately direct therapy. Antibiotics may be changed during the course of treatment based on more recent culture and susceptibility results or the patient's clinical response. It is important to note, however, that susceptibility testing in vitro does not necessarily correlate with clinical response.

Infections caused by *P. aeruginosa* in patients with CF are usually treated with two antibiotics of different classes in an attempt to prevent the emergence of resistance and in the hopes of achieving synergy. However, using the results from testing for susceptibility to multiple drug combinations does not confer any advantage to clinician-selected combinations of antibiotics, and multiple drug combination synergy testing is no longer routinely recommended.[135] The most common combination of intravenous therapy for *P. aeruginosa* involves the use of an aminoglycoside with a β-lactam antibiotic. Higher doses of systemic aminoglycosides are required in patients with CF because of increased clearance and altered pharmacokinetics[136] so drug concentrations must be monitored and maintained in the therapeutic window. For CF patients with multidrug-resistant *P. aeruginosa,* colistin may be used intravenously, but its use requires close monitoring for neurological symptoms and renal toxicity. Concurrent intravenous aminoglycoside therapy should be avoided with intravenous colistin. Oral fluoroquinolones are frequently used, but *P. aeruginosa* can develop resistance rapidly.[118] Inhaled antibiotics can be used in conjunction with either intravenous or oral therapy depending on antibiotic sensitivities.

Length of antibiotic therapy is determined by resolution of symptoms and return of lung function to its previous baseline or to a new plateau. Concern for emergence of resistant organisms limits extending courses beyond these endpoints. Complete eradication of organisms in the chronically infected patient is not achievable in most patients. Typically, return of lung function to baseline and resolution of symptoms can be achieved with 10–21 days of therapy with the majority of patients receiving 2 weeks of antibiotics, although little data is available that precisely defines adequate length of therapy.[131,137]

Suppressive or maintenance therapy with inhaled antibiotics is appropriate for the majority of patients who are chronically infected with *P. aeruginosa.* Inhaled tobramycin administered on an alternate month basis led to a significant improvement in lung function.[120] Additionally, emergence of tobramycin resistance is low when employing this strategy. Similar improvement in $FEV_1$ was described with inhaled aztreonam.[138] Aerosolized colistin has been used and this route minimizes the risk of systemic toxicity.[139]

Infection with nontuberculous mycobacteria is a growing concern.[140] Finding "atypical" mycobacteria presents a perplexing problem for the CF clinician trying to determine whether this organism is colonizing the airway or is acting as a pathogen; many of the presenting symptoms and radiographic findings can be explained by the more commonly isolated bacteria. In addition, therapy for nontuberculous mycobacteria involves prolonged treatment with multiple antibiotics, each of which has associated toxicities and variable tolerability. The recommended approach is to first treat the other organisms found on culture and closely monitor the patient's response to this therapy. When nontuberculous mycobacteria are cultured from a patient with CF, it is recommended that routine macrolide therapy be discontinued to prevent the emergence of resistance. The long-term implication of the presence of nontuberculous mycobacteria in the CF airway is unclear.[141]

## Cystic Fibrosis Transmembrane Conductance Regulator Modulators

Treatment of CF is increasingly based on the specific CFTR defect, which is defined by the mutation class (Fig. 51.7). Ivacaftor, the first

US Food and Drug Administration (FDA)-approved therapy to address the basic defect in CF, is a small molecule potentiator. In patients with the G551D mutation, a class III gating mutation, it decreased sweat chloride concentrations by 48 mmol/L and improved percent predicted $FEV_1$ by 10.6 percentage points compared to placebo.[110] In addition, there was a 55% decrease in pulmonary exacerbations as well as significant changes in weight gain and Cystic Fibrosis Questionnaire–Revised (CFQ-R) respiratory domain scores. Similar improvements were documented in a subsequent trial of patients with most other class III mutations.[111] However, when studied in patients with the R117H mutation, a class IV mutation, the results were mixed. Improvement was documented in both sweat chloride concentrations and CFQ-R scores, while $FEV_1$ percent predicted improved significantly only in subjects older than 18 years of age, but not in children.[142]

Class 4: Mutants that have altered channel properties, e.g., R117H
Class 3: Regulatory mutants that fail to respond normally to activation signals, e.g., G551D
Class 6: Mutants near the N- or C-terminus that lead to altered membrane insertion or trafficking, e.g., 4279insA
Class 2: Misfolding mutant CFTR degraded in the endoplasmic reticulum, e.g., delF508
Class 1: Premature termination of CFTR mRNA translation, e.g., S489X
Class 5: Decreased functional CFTR synthesis or transport, e.g., A455E

**FIG. 51.7** Schematic diagram showing the classes of

cystic fibrosis transmembrane conductance regulator (CFTR) mutations. *ER*, Endoplasmic reticulum. (Modified from Pittman JE, Ferkol TW. The evolution of cystic fibrosis care. *Chest.* 2015;148:533-542.)

For class II mutations, such as the common ΔF508, lumacaftor, a small molecule corrector designed to chaperone the defective CFTR protein, was combined with ivacaftor. This combination therapy reduced the number of pulmonary exacerbations and hospitalizations but demonstrated only a modest, albeit statistically significant, improvement in $FEV_1$.[112] This combination therapy appears to destabilize the corrected ΔF508 CFTR *in vitro.*[143] Similar decreases in plasma membrane density of ΔF508 CFTR with concomitant loss of chloride conductance was seen when ivacaftor was combined with VX-661, another corrector.[144]

Class I mutations are nonsense mutations resulting in the absence of CFTR production; several agents allow the ribosome to read through the premature stop codon but not through normal termination codons. A phase III study using a candidate drug (PTC124) did not demonstrate significant improvement in lung function or in the number of pulmonary exacerbations compared to placebo. However, post hoc subgroup analysis showed that in those subjects not using chronic inhaled tobramycin, there was an improvement in both of those measures.[145] A follow-up multinational, multicenter study in subjects not treated with inhaled tobramycin is underway.

## Antiinflammatory Therapy

Several decades ago, CF caregivers noted that patients with CF who were hypogammaglobulinemic tended to have less severe lung disease than those with elevated serum IgG concentrations,[146] which supported the hypothesis that an overzealous immune response in patients with CF may be deleterious and provided rationale for early trials with antiinflammatory therapy. Two studies using systemic corticosteroids demonstrated an improvement in lung function over placebo.[147,148] However, excessive side effects were noted during the larger second study, including diabetes, cataracts, and growth failure, even during alternate-day dosing. Multiple studies have examined the potential use of inhaled corticosteroids in patients with CF, but they failed to show benefit.[149]

High-dose ibuprofen slows the annual rate of decline in lung function with the greatest effect seen in school-age children.[150] Even though the risks associated with its use, gastrointestinal hemorrhage and renal failure, are small, they are so dramatic that few CF centers have adopted this treatment.

Azithromycin is known to possess antiinflammatory effects, but its exact mechanism of action in CF is unclear. Studies in CF patients over 6 years of age infected with *P. aeruginosa* in whom azithromycin was administered thrice weekly demonstrated better lung function, weight gain, and fewer pulmonary exacerbations compared to placebo.[151] A recent study in patients not chronically infected with *P. aeruginosa* failed to demonstrate a difference in lung function, but they did show a 50% reduction in pulmonary exacerbations compared to placebo.[152] Adverse effects have been minimal, and this agent has gained widespread acceptance; however, data analysis from a recent study not designed for this specific question has raised concerns that azithromycin may antagonize the beneficial effects of inhaled tobramycin.[153] A study to test this hypothesis is underway.

Other novel approaches include addressing the depletion of antioxidants in the neutrophils and airway surface liquid in patients with CF. *N*-acetlycysteine, a glutathione prodrug, given orally in high doses did not decrease sputum elastase activity in patients with CF, but it did stabilize lung function compared to placebo.[154] A large multicenter study to better evaluate this agent is presently underway.

Antiinflammatory therapy in CF patients must be approached cautiously, since the immune system does contain infection within the lung. A clinical trial with a leukotriene B4 antagonist was terminated early because the treatment group had more pulmonary exacerbations requiring hospitalizations.[155] Another trial examining the efficacy of nebulized interferon $\gamma$1B also increased hospital admissions.[156] Identifying a safe and effective antiinflammatory treatment will continue to be an active area of research in CF, and three antiinflammatory agents with different mechanisms of action are in phase 2 trials.

## Preventative Care

Prevention of complications remains a priority for CF clinicians. The adoption of newborn screening in the United States has had a significant impact on care and has expanded traditional prophylaxis to include presymptomatic identification of nutritional and respiratory complications. While prevention of illness with immunization remains a significant focus, avoiding nutritional deficiencies and eradication of *P. aeruginosa* have become active areas of both research and quality improvement.

Routine immunization is an important component of CF care. Although systematic reviews have failed to demonstrate long-term benefit of immunization, the impact of influenza can be substantial, and yearly vaccination continues to be recommended.[157,158] Similarly, respiratory syncytial virus infection is associated with more severe respiratory complications, thus prevention using palivizumab should be considered in all children less than 2 years and it is recommended in high-risk patients.[159]

Nutritional interventions have resulted in improved outcomes. Better growth parameters at age 3 are associated with improved lung function at 6 years of age.[95] Whereas earlier recognition by newborn screening has demonstrated improved growth and improved pulmonary outcomes in small single-center cohorts,[160,161] confounders may have prevented the demonstration of any long-term benefit.[162] However, a reduced treatment burden may result from earlier diagnosis with an overall improvement in outcome.[163]

Antibacterial prophylaxis remains a controversial topic. A trial with cephalexin to prevent early *S. aureus* infection did not improve health outcomes and unexpectedly increased *P. aeruginosa* infection.[164,165] However, the latter effect has not been reported elsewhere. Several antipseudomonal vaccines have been developed, but they failed to show clinical effectiveness in protecting against *P. aeruginosa* infection.[166] Although its benefit to CF patients is unclear, antipneumococcal vaccination should be performed as a routine childhood immunization.[167]

## Lung Transplantation

Although we have witnessed great improvements in median survival over the past decade, there are still patients with CF who progress to advanced lung disease and respiratory insufficiency at a very young age. For these children and adolescents, replacement of their damaged lungs with new lungs is their only hope to prolong survival and improve their quality of life. In 2014, a total of 205 adults and children with CF underwent bilateral lung transplantation in the United States. Unfortunately, the benefits of lung transplantation remain limited, with 5-year survival rates remaining at approximately 50%.[168,169] While there are many factors associated with success, if lung transplantation is to truly extend life, appropriate timing of the procedure is paramount. For more than 20 years, transplant referrals have been made when $FEV_1$ reaches 30% predicted for age; although several alternative models have been proposed to predict survival with CF, none are substantially better than others.[102,170]

Transplant physicians grasped the importance of these predictor models early in determining the appropriate time to list patients for transplantation. Before 2005, the lung allocation system in the United States was based on time spent waiting on the list. Since then, donor lungs have been allocated using the lung allocation score,[171] derived from variables that include forced vital capacity, body mass index, age, renal function, diabetes, supplemental oxygen, and assisted ventilation. Since implementation, CF patients 12 years and older have organ allocation based on their clinical status and not time on the wait list. Nevertheless, despite this more equitable system of organ distribution, the supply of donors is limited, and patients still die waiting for donor lungs.

Contraindications to lung transplantation for CF vary based on individual center experience or emergence of new information. Because of poor posttransplant outcomes, some centers will consider the presence of *B. cenocepacia* or *B. dolosa* as absolute contraindications. The need for invasive positive pressure ventilation before transplant is no longer considered an absolute contraindication to transplantation at many centers. Short-term outcomes regarding morbidity and mortality are worse in patients requiring ventilatory support, but long-term outcomes do not appear to be impacted.[172] Rather than maintaining a patient in respiratory failure on mechanical ventilation, many transplant centers now opt for ambulatory extracorporeal support to maximize the patient's rehabilitation potential and improve posttransplant outcomes. Multiorgan failure is a contraindication to lung transplantation, but for CF patients with both advanced liver disease and end-stage lung disease, simultaneous liver-lung transplantation is feasible, with outcomes as good if not better than lung transplantation alone.[173]

## Emerging Therapies

Improved clinical outcomes in CF patients are encouraging (discussed in more detail in Chapter 53). In 2015, the number of adults in the Cystic Fibrosis Patient Registry was greater than the number of children, a testament to the progress being made with the widespread institution of conventional therapies alone. Although there are many therapies in the CFF drug development pipeline, our focus in this section is to describe agents that have the potential to more proximally correct the basic ion transport defect, including modulation or correction of defective CFTR and activation of other ion channels.

Somatic gene therapy is a potential strategy for correcting CF. More than 20 clinical gene therapy trials were conducted in the United States, with disappointing results. Many obstacles to airway gene therapy need to be overcome, including airway obstruction that prevents vector delivery to the epithelial or submucosal gland cells, incitement of acute inflammatory and immune responses that interfere with repetitive dosing, and inefficiency of gene delivery to the airway epithelium. A consortium in UK recently examined the efficacy of a nonviral, liposomal gene transfer vector in CF adolescents and adults in a randomized, double-blind, placebo-controlled, phase 2b trial and found a modest difference in $FEV_1$, which may be related to a marked decline in pulmonary function measures in the placebo group.[174] In addition, the absence of evidence showing CFTR transgene delivery or expression raises questions about the success of the trial. Nevertheless, this research continues.

More recently, newer forms of gene editing, such as clustered regularly interspaced short palindromic repeats (CRISPR), which relies on Cas9 nucleases to recognize and cut genetic elements or insert desired sequences, has been widely used for genomic engineering in vitro,[175] but their application to the treatment of CF lung disease is still premature. These approaches have the same delivery limitations as gene therapy.

# Prognosis

Survival of patients with CF has improved dramatically since it was first described over 70 years ago. While gastrointestinal signs and symptoms tend to predominate early, sinopulmonary manifestations increase with age. The progressive lung disease leads to considerable morbidity and respiratory failure and accounts for the vast majority of CF deaths.[109] In the United States, the predicted survival has steadily increased and now exceeds 40 years.[1,176] This improvement is related to advances in monitoring and better, more aggressive treatment strategies. Thus, routine surveillance studies are recommended in the care of children with CF, which include regular spirometry to monitor lung function, chest radiographs, and sputum or oropharyngeal cultures to assess lower respiratory tract flora.

Factors that negatively affect prognosis include malnutrition,[177] diabetes mellitus,[178] infection with *P. aeruginosa*,[179,180] *B. cepacia* complex,[26,181] and the frequency of pulmonary exacerbations.[179] There is a gender gap in CF, and males tend to do better than female counterparts.[182,183] Socioeconomic status can influence survival of CF patients, and environmental factors, such as exposure to tobacco smoke and airborne pollutants, have detrimental effects.[184,185] Conversely, patients with atypical or pancreatic-sufficient forms of the disease have slower decline in pulmonary function when compared to those with classical CF; their prognosis and long-term survival are better.[186]

As the benefits of CF newborn screening become more widely evident, we expect that the progression and extent of nutritional failure and lung disease can be slowed. Preliminary small-cohort studies support that early recognition and nutritional intervention results in not only more rapid growth recovery but also in associated respiratory benefit.[187–189]

## Conclusions

Pulmonary disease in CF is the consequence of defective function of apical ion channels and impaired mucociliary clearance, which renders the airway susceptible to endobronchial bacterial infection and induces an intense inflammatory response that leads to bronchiectasis and ultimately respiratory failure. Children with CF born today have greater potential to live longer, primarily because of earlier diagnosis and multidisciplinary, center-based care, where children can benefit from treatments for downstream consequences of defective ion transport, such as inhaled mucolytics, antibiotics, antiinflammatory agents, and airway clearance techniques. More recently, newer therapeutics have emerged that target the basic defect and have shown promise in early clinical trials. If successful, these treatments are poised to profoundly change the course of CF lung disease.

## 52

# Nonpulmonary Manifestations of Cystic Fibrosis

*Amy Michelle Garcia MD, MS, Jill Dorsey MD, MS*

Although lung disease continues to be the main cause of morbidity and mortality, gastrointestinal complications have become increasingly important in the care of individuals with cystic fibrosis (CF). Thus it behooves caregivers to become familiar with the effects of CF outside of the lungs. This chapter presents a summary of the current knowledge of the extrapulmonary manifestations of CF with focus on the gastrointestinal and endocrine systems.

## Pancreatic Disease

### Pathobiology

The pancreas is composed of endocrine cells that secrete hormones, exocrine cells that make digestive enzymes, and duct cells that secrete bicarbonate and water. The exocrine pancreas consists of cells organized into acini and a duct system that leads to the small intestine. The pancreatic juice secreted from the duct cells is clear, colorless, and nearly isotonic. In both animals and humans, bicarbonate seems to drive fluid secretion by the pancreatic ducts.[1]

Bicarbonate allows the highly concentrated proteins that are secreted by the pancreatic acinar cells to remain in a soluble state. Moreover, bicarbonate is important for neutralizing gastric acid to create the optimal pH for pancreatic enzymes, bile acids, and micelles. The adult pancreas normally secretes 1–2 L of a bicarbonate-rich fluid each day. The basis of the bicarbonate secretion relies on the exchange of luminal chloride for bicarbonate, but the exact mechanism is still not fully understood. The CF transmembrane conductance regulator (CFTR) protein is located in the apical membrane of the epithelial cells of the pancreatic ducts. The apical $Cl^-/HCO_3^-$ exchanger is dependent on the expression of CFTR,[2] which functions as the apical $Cl^-$ channel.[3] Most likely, the apical anion exchanger in the pancreatic duct cells is a member of the SLC26 family.[4] A physical association between SLC26A6 and CFTR has been suggested due to the presence of a PDZ domain at the C terminus of SLC26A6, which is identical to that of CFTR.[5] Furthermore, they both bind through the PDZ motif to scaffolding proteins. It is possible that SLC26A6 and CFTR interact through these scaffolding proteins, allowing CFTR to stimulate the apical anion exchange.[2] However, the classic proposal of a 1 : 1 exchange of $Cl^-/HCO_3^-$ cannot explain the large sustained secretion of bicarbonate. Two of the members of the SLC26 family, SLC26A3 and SLC26A6, have been proposed to work in conjunction to achieve normal bicarbonate secretion. SLC26A3 secretes $Cl^-:HCO_3^-$ in a ratio of 2 : 1, whereas the ratio by SLC26A6 is 1 : 2. This information, combined with the location of SLC26A6 at the proximal ducts and SLC26A3 at the distal ducts, may explain the high bicarbonate concentration found in normal pancreatic juice.[6] However, it does not appear that the combination of the two exchangers are able to reach the necessary concentration of luminal bicarbonate.[7] Alternatively, the activation of the WNK1-OSR1/SPAK (protein kinase with no lysine 1-oxidative stress response kinase 1/sterile20-related, proline-alanine rich kinase) pathway causes CFTR to become permeable to $HCO_3^-$, which allows for the generation of the necessary concentration of 140 mmol/L of $HCO_3^-$ of normal pancreatic juice.[8]

Dysfunction of CFTR, as in CF, results in impaired electrolyte transport and thus a reduction in fluid secretion. Thus the pancreatic juice in individuals with CF is significantly more concentrated then controls.[9] These thickened secretions then lead to obstruction of the pancreatic ducts, as well as inflammation and injury (Fig. 52.1).

Under normal circumstances (A) Cl$^-$ and HCO$_3^-$ secretion provides a driving force for the movement of fluid into the lumen of the duct, which maintains the solubility of secreted proteins in a dilute, alkaline solution. In CF (B), impaired anion transport results in decreased secretion of more acidic fluid, which leads to precipitation of secreted proteins. Intraluminal obstruction of the ducts then causes progressive pancreatic damage and atrophy.

**FIG. 52.1** Pathophysiology of pancreatic disease in cystic fibrosis.

## Pancreatic Insufficiency

Pancreatic insufficiency (PI) occurs when the amount of digestive enzymes delivered to the intestine is inadequate for nutrient digestion. Steatorrhea, the presence of excess fat in the stool, then occurs. Infants with PI at diagnosis often have decreased weight gain, minimal fat stores, and reduced serum albumin and blood urea nitrogen (BUN) levels.[10] Children with PI may present with growth failure, weight loss, abdominal bloating, foul-smelling stools, edema, or diarrhea. Parents of children who are toilet-trained may report that the stools appear to be floating due to the high fat content of the stool, although stools may float due to increased air content, and this is seen in other conditions as well. It is possible that with mild PI, stools appear normal. Imaging of the pancreas will show atrophy with replacement by fatty tissue in individuals with PI.

CF is the most common cause of PI in childhood. Approximately two-thirds of children with CF are pancreatic insufficient at birth, and approximately 90% will develop PI by 1 year of age.[10] Individuals with two mutations from class I, II, or III CFTR mutations typically have severe pancreatic disease resulting in PI.[11] In patients with severe disease, the obstruction and destruction of exocrine function begins in utero. The damage to the pancreas that occurs in utero forms the basis for newborn screening for CF disease. Serum immunoreactive trypsinogen (IRT) is a precursor to trypsin that is elevated in the blood of infants with CF.[12] When pancreatic dysfunction is present, release of pancreatic enzymes is impaired, and IRT accumulates in the blood stream. Therefore most infants with CF have elevated blood levels of IRT. It has been shown that children who develop PI and those diagnosed with PI in early infancy have similar patterns of IRT levels.[13] One study found that IRT determinations alone were not sufficient to demonstrate differences between mild and severe disease in the first year of life, suggesting ongoing pancreatic damage, and thus elevated IRTs, in both groups.[14]

## Pancreatic Sufficiency

Approximately 10%–15% of individuals with CF produce sufficient amounts of pancreatic enzymes to prevent malabsorption of nutrients and are considered to be pancreatic sufficient (PS). These individuals tend to have at least one of the CFTR mutations that are associated with mild pancreatic disease (class IV or V).[15] However, if only one mild CFTR mutation is present, then this does not exclude the possibility of developing PI in the future.[16] On average, sweat chloride levels are lower in individuals with PS as compared with those with PI. Individuals with PS also tend to have less severe lung disease and better nutritional status than those who have PI. With milder disease, the diagnosis of CF tends to occur later in childhood or early adulthood. Twenty percent of individuals with CF who are PS will develop pancreatitis.[17] The diagnosis of pancreatitis may, in some cases, precede the diagnosis of CF.[18]

## Assessment of Pancreatic Function

Every individual with CF should be screened for PI at diagnosis. In addition, individuals with at least one severe CFTR mutation (class I, II, or III) should be screened at least annually for PI. Evaluation of pancreatic function can be made by direct or indirect testing. Direct testing requires stimulation of the pancreas (with secretin, cholecystokinin, or both) and collection of pancreatic fluid for analysis. To obtain pancreatic fluid for direct testing, a tube or an endoscope must be placed in the small intestine, which is invasive and often requires sedation. In children who require long-term follow-up for their PI, repeated invasive testing is not feasible. Indirect tests are noninvasive and less costly, so they are typically preferred. However, with mild pancreatic exocrine dysfunction, indirect testing can be less sensitive and specific.[19] In contrast, direct stimulation of the pancreas with secretin has high sensitivity and specificity in identifying PI.[20]

The 72-hour quantitative fecal fat balance method has been used as an indirect test to diagnose PI. If fecal fat excretion is more than 15% of total fat intake in infants less than 6 months of age, and 7% in older infants, then malabsorption is present. Compliance remains an issue with this test because it requires a 3- to 5-day stool collection and a complete dietary history. In addition, most patients with fat malabsorption have diarrhea, which makes complete collection difficult, especially in infants with absorbable diapers. Due to these limitations, alternatives to the fecal fat balance test have been sought. The most commonly used of the indirect tests is fecal pancreatic elastase-1. Children do not have to stop pancreatic enzyme supplementation to complete this test. However, the presence of intestinal villous atrophy, as in celiac disease, or acute episodes of diarrhea can lead to falsely low values.[21,22] The specificity and sensitivity of fecal pancreatic elastase-1 in a pediatric CF cohort is 100% when a value of less than 100 µg/g is used.[23] The specificity of this test was lower in individuals with non-CF pancreatic disease (e.g., Shwachman-Diamond syndrome). Overall, the negative predictive value was 99%. An empiric trial of pancreatic enzyme replacement therapy (PERT) in an individual with a strong clinical history of PI could also be considered.

## Management of Pancreatic Insufficiency

In CF, treatment for PI focuses on optimizing PERT to promote absorption of nutrients and fat-soluble vitamins. In 1991 the US Food and Drug Administration (FDA) mandated that all pancreatic enzymes be approved; prior to the enactment of FDA standards in 2010, PERT was not regulated. Currently, six approved products are available. Each product includes a combination of lipase, protease, and amylase. These enzymes are in the form of granules or microspheres with a pH-sensitive coating to allow release in the alkaline environment of the small intestine. Dosing for PERT is based on the lipase component. Because of this, it is not advisable to use an unregulated generic or nonproprietary preparation because the amount of lipase can potentially vary even in the same product. More importantly, enzyme dosage should not exceed 2500 lipase units/kg per meal or 4000 lipase units/g fat per day (10,000 lipase units/kg/day total) to avoid fibrosing colonopathy.[24] Fat-based dosing of PERT relies more on the number of fat grams per meal or snack than the person's weight. This method may be more applicable for infants ingesting around the same amount every day and individuals with tube feedings or reliance on packaged foods.

The dose should be no more than 2500 lipase units/kg per feeding, with a maximum daily dose of 10,000 lipase units/kg.[24] Caution should be used to avoid prolonged contact of the enzymes with the oral mucosa because this may cause ulceration. If the capsule needs to be opened, the microspheres should be administered with a food that can be swallowed whole (like applesauce, gelatins, or pureed bananas that do not require chewing) and the mouth should be inspected after to ensure no retention of any beads. PERT should be taken just prior to the start of a meal or snack. If the individual continues to have abnormal stools, bloating, or belly pain, despite PERT, dosing may be adjusted until the maximum daily dose is reached. If symptoms continue despite maximum dosing, then acid suppression therapy may be tried to help the enteric coating of the PERT dissolve by providing a more alkaline environment. The provider should keep in mind the significant potential side effects of these medications (tachyphylaxis with H2 receptor antagonists; increased susceptibility to pneumonia, increased susceptibility to *Clostridium difficile,* and possible impact on bone health with the proton pump inhibitors). If clinical symptoms persist, then the provider should investigate further for other etiologies such as small bowel bacterial overgrowth, constipation, celiac disease, or chronic giardiasis.

## Fibrosing Colonopathy

Fibrosis and thickening of the colon wall in a circular and intramural fashion is another unique clinical problem of patients with CF. The pathophysiology behind this development of fibrosing colonopathy remains uncertain, although there is a noted correlation with the use of high PERT dosing, most especially if the dosing exceeds 50,000 lipase units per kilogram per day.[25] Other risk factors associated with this phenomenon include a young age (between 2 and 7 years), previous history of intestinal surgery, meconium ileus (MI), or prior occurrence of distal intestinal obstruction syndrome (DIOS).[25,26] These associations were brought to light in the United States in the early 1990s, as there was an increased incidence that subsequently led to a review of these cases and the CF patient registry.[25] The colonic wall thickening results in decreased motility and narrowing of the lumen that can sometimes lead to stricture. Clinical symptoms may vary though the most common include abdominal pain with concern for colonic obstruction that may or may not involve emesis. Other clinical signs may include constipation, diarrhea, hematochezia, anorexia, and failure to gain weight as expected. Abdominal ultrasound, barium enema, magnetic resonance scans, and endoscopies can all be used to help make this diagnosis.[26]

## Treatment of Fibrosing Colonopathy

Antiinflammatory treatments including prednisone pulses and antibiotics have been used with varying success.[26] In extreme cases the use of balloon dilation or surgical resection of the fibrosed portion of the colon may be necessary.[25,26] There is consensus on limiting doses of PERT to 2500 lipase units per meal or 10,000 lipase units per kg per day.[24,25]

# Pancreatitis

Acute pancreatitis requires the presence of preserved pancreatic tissue. Thus pancreatitis tends to occur in 20% of PS individuals with CF and is rare in those with PI. It typically occurs in adolescence and young adulthood and may be the first manifestation of CF.[17,27] A two-hit model has been proposed to explain the development of pancreatitis in CF. CFTR dysfunction leading to ductal obstruction and inflammation makes up the first hit, whereas acinar damage from alcohol, drugs, or hypercalcemia leads to the second hit. It has been shown that there is decreased bicarbonate flow through pancreatic ducts in patients with CF and PS with preserved pancreatic mass.[28] Furthermore, a study demonstrated that during alcohol-induced pancreatitis, CFTR expression is decreased on pancreatic ductal epithelial cells.[29]

The diagnosis of acute pancreatitis can be made when two of the three following criteria are met: epigastric abdominal pain that may radiate to the back, an increase in amylase or lipase that is greater than 3 times the upper limit of normal, and typical findings on imaging. If possible, nutrition should be maintained during treatment and follow-up.

## Hepatobiliary Disease

CFTR is found on the apical membrane of intrahepatic and extrahepatic bile ducts, as well as the gallbladder, but not on the hepatocytes.[30] How CFTR mutations lead to liver fibrosis is unclear. It has been proposed that the dysfunctional CFTR leads to thickened secretions and obstruction of intrahepatic bile ducts. This would allow for the accumulation of toxic bile acids that may activate hepatic stellate cells, via monocyte chemotaxis protein-1, which then produce increased periductular collagen.[31,32] This focal portal fibrosis is the pathognomonic histopathologic liver lesion in CF.

Cystic fibrosis liver disease (CFLD) encompasses a number of different liver disorders, from elevated liver enzymes to multilobular cirrhosis (advanced liver disease). Only approximately 5%–10% of individuals with CF will develop multilobular cirrhosis (Fig. 52.2).[33] Thus the vast majority has clinically insignificant hepatobiliary disease. In fact, 40%–50% of individuals with CF have intermittent elevations in their aspartate aminotransferase (AST), alanine aminotransferase (ALT), or gamma-glutamyl transferase (GGT) that can be up to 2.5 times the upper limit of the reference range but do not predict the presence or development of significant liver disease. Interestingly, these same blood tests may be normal in the setting of multilobular cirrhosis.[34]

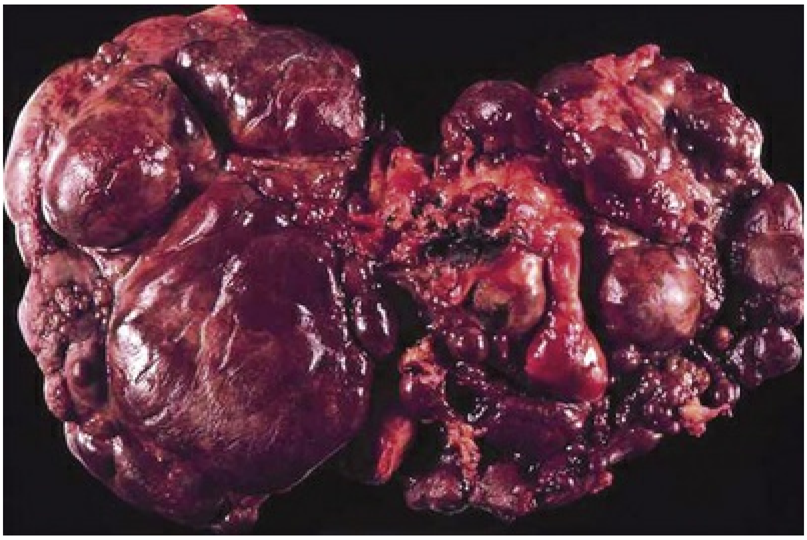

**FIG. 52.2** Liver explant from an individual with cystic fibrosis demonstrating multilobular cirrhosis.

CFLD occurs most commonly in individuals with class I, II, or III mutations on both alleles,[35] although there does not appear to be a strong correlation between genotype and phenotype. Perhaps additional genetic factors (modifier genes) and environmental factors play a role in the development of significant liver disease.[34] For example, an increased risk of cirrhosis was found in those carrying a single copy of the SERPINA1 Z allele (the PiZ heterozygote state for alpha-1 antitrypsin).[36] CF patients who are carriers of the Z allele have an increased population attributable risk of 7% for multilobular cirrhosis, but this only accounts for approximately 9% of CF patients with cirrhosis.

A history of MI was thought to be a risk factor for the development of CFLD. However, more recent studies have not confirmed this association.[37,38] Male gender and PI have also been thought to be associated with CFLD.[39]

## Clinical Presentation of Liver Disease

Liver disease in CF is often subclinical and the majority of individuals are asymptomatic until the development of advanced disease. Advanced CFLD typically develops around 10 years of age and is often slowly progressive.[40] CFLD accounts for 2.8% of overall mortality in the CF population.[41] Physicians should remain vigilant for signs of advanced liver disease such as splenomegaly or thrombocytopenia.

A thorough physical examination should be completed with every visit because the most common clinical finding in CFLD is hepatomegaly on routine physical examination. The liver may be felt 2–3 cm below the right costal margin or the xyphoid, with enlargement potentially limited to the right or left lobe. The examiner may note that the liver is firm and nodular. If the liver feels smooth, the hepatomegaly may be the result of fatty infiltration of the liver, which is felt to be a benign condition. However, given the recent studies of the progression of nonalcoholic steatohepatitis to cirrhosis, the implications of hepatic steatosis in CFLD may change.[42] It also should be noted that a cirrhotic liver tends to be small and therefore no hepatomegaly may be found on abdominal examination. Even without hepatomegaly, the physician could still be guided towards the diagnosis of significant liver disease by the presence of splenomegaly, resulting from portal hypertension, a late complication of cirrhosis.

Besides hepatosplenomegaly, other signs of liver disease are less common on physical examination. Spider nevi, palmar erythema, jaundice, edema, distension of abdominal wall veins, and ascites can be seen with chronic liver disease. These manifestations are found in more advanced disease with the exception of jaundice in early infancy. Cholestasis, or elevation in the conjugated bilirubin, tends to be the earliest manifestation of liver involvement in CF occurring in 2% of infants with CF. Cholestasis generally resolves within 3 months but occasionally can mimic biliary atresia.[43]

## Diagnosis of Liver Disease

Early diagnosis of CFLD remains problematic even with published guidelines for the management of liver and biliary tract disease in CF.[44] Unfortunately, there are no tests currently available to identify individuals with CF who are at high risk of developing liver cirrhosis. In general, the combination of physical examination findings, biochemical results, and imaging are used to make the diagnosis of CFLD.

Routine annual blood work may reveal an elevation in AST, ALT, or GGT. As mentioned earlier, intermittent elevations in these values are common and do not necessarily indicate significant liver disease. Normal values may even be found in the setting of multilobular biliary cirrhosis.[34] However, persistent elevation of AST, ALT, or GGT greater than three times the upper limit of normal is rare.[45] Elevation of AST and ALT, with normal GGT, may indicate hepatic steatosis. The possibility of hepatic steatosis should prompt further testing for deficiencies in essential fatty acid, carnitine, and choline, as well as assessment for malnutrition. However, hepatic steatosis can also be present in individuals with adequate nutritional status.[46] Elevation of alkaline phosphatase without an elevation in GGT can be found in growing children and does not indicate liver disease.[47,48]

The AST to platelet ratio index (APRI) has been studied in the setting of non-CF–related liver disease as a noninvasive marker of liver fibrosis and cirrhosis. More recently, investigators looked at APRI as a predictor of liver fibrosis in individuals with CF. They found that APRI correlated well with severe fibrosis but tended to overestimate earlier stages of fibrosis.[46]

In general, further evaluation should be considered if an individual's ALT or GGT remain elevated for 6 months or more.[45] At that time, it would be prudent to evaluate for other causes of liver disease such as alpha-1 antitrypsin deficiency, celiac disease, autoimmune disease, Wilson disease, chronic viral hepatitis, primary sclerosing cholangitis, drug toxicity, and toxins. Evaluation of liver synthetic function should also be checked with albumin, prothrombin time (PT), international normalized ratio (INR), and glucose. However, only approximately 10% of individuals with CF and cirrhosis will develop synthetic failure.[49]

Doppler ultrasound of the liver should be ordered when CFLD is suspected. This noninvasive modality provides information about the appearance of the liver without any radiation exposure, which is preferred in this CF population, which is often exposed to chest x-rays and computed tomography (CT) scans of the chest. A homogeneous pattern is typically associated with hepatic steatosis.[50] However, it is important to keep in mind that periportal steatosis and focal fibrosis have a similar appearance on ultrasound.[44] Individuals with heterogeneous parenchyma of the liver found on ultrasound are thought to be at increased risk for development of cirrhosis.[51] A pattern indicative of cirrhosis of the liver, including heterogeneous echogenicity and coarse echo texture of the liver parenchyma accompanied by nodularity of the liver contour, can also be found. Surprisingly, 3.3% of individuals with CF, not known to have cirrhosis, were found to have a cirrhotic pattern on ultrasound in a prospective, multicenter study of using ultrasound to predict hepatic fibrosis. The investigators found that an abnormal ultrasound liver pattern was associated with CF-related diabetes, whereas a normal ultrasound was associated with early *Pseudomonas aeruginosa* infection.[52] However, a normal liver ultrasound does not preclude significant liver fibrosis.[53]

The liver Doppler ultrasound also provides information about CFLD by documenting the flow patterns of the vasculature, as well as the presence of dilatation. Hepatofugal flow (away from the liver) in the portal vein, as well as recanalization of the umbilical vein, suggests advanced portal hypertension. Ultrasound can also detect thrombosis of the portal or splenic veins which leads to splenomegaly. Finally, increased right heart pressure leading to hepatomegaly may be suggested by dilated hepatic veins.[44]

Magnetic resonance imaging (MRI) and abdominal CT both provide useful information regarding hepatic steatosis versus fibrosis. Because MRI does not require radiation, it is generally preferred over CT. Even though CT is not the test of choice, the liver is often seen on unenhanced CT of the chest (Fig. 52.3). Transient elastography (FibroScan) is another noninvasive technique that uses ultrasound, rather than radiation, to quantify liver stiffness which correlates with liver fibrosis. Furthermore, magnetic resonance cholangiography (MRCP) allows evaluation of the intrahepatic and extrahepatic bile ducts. Thus a beaded appearance to the intrahepatic ducts, suggestive of sclerosing cholangitis, or choledocholithiasis can be seen with MRCP.

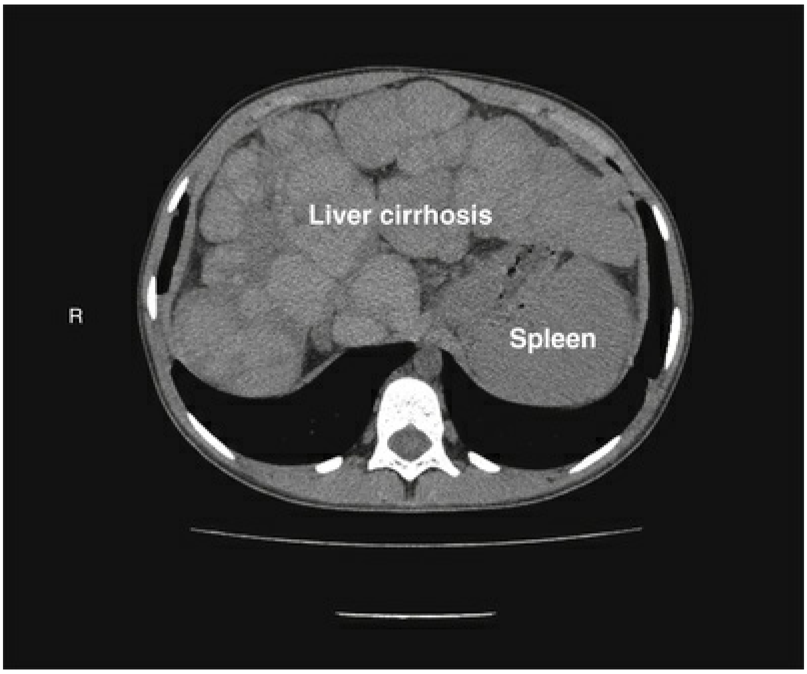

**FIG. 52.3** Computed tomography scan of an individual with cystic fibrosis demonstrating cirrhosis of the liver.

Liver biopsy is viewed as the gold standard for the diagnosis of a variety of non-CF–related liver diseases. However, in CFLD, the disease tends to be patchy and sampling error is possible.[47] Obtaining two cores, or dual pass, has been advised for evaluation because it improves detection of fibrosis by 22% compared with a single core.[54] Liver biopsy tends to be helpful when there is a question of an additional or alternative disease process, for determining the extent of fibrosis, or for identifying the predominant liver lesion (steatosis or focal biliary cirrhosis [FBC]).[44,46] The liver biopsy can demonstrate focal portal fibrosis and inflammation, cholestasis, and bile duct proliferation in FBC, which is primarily a histologic diagnosis that is often clinically silent.[55] FBC is the pathognomonic histopathologic liver lesion in CF and may rarely progress to multilobular cirrhosis.

## Management of Liver Disease

Unfortunately, a therapy to slow down or reverse fibrosis in CFLD has not been identified. Current management focuses on supportive care and addressing complications of advanced liver disease. Prevention of concomitant liver disease by ensuring complete vaccination against hepatitis A and hepatitis B is also essential to the treatment of individuals with CFLD.

The use of ursodeoxycholic acid (UDCA) in CFLD remains controversial. The proposed benefits include improved bile flow, displacement of toxic hydrophobic bile acids, cytoprotection, and stimulation of biliary bicarbonate secretion. UDCA is typically well tolerated, although the side effect of diarrhea has been reported. Typical dosing of UDCA is 20 mg/kg per day divided into two doses.

However, a 2014 Cochrane review did not find sufficient evidence to recommend routine use in individuals with CF. Specifically, this review underlined the paucity of randomized controlled trials evaluating the effectiveness of UDCA in CF. The available studies did not assess prevention of liver disease in individuals with CF, portal hypertension, liver transplantation, or survival.[56] Furthermore, a study evaluating high-dose UDCA (28–30 mg/kg per day) in primary sclerosing cholangitis was terminated due to an increase risk of death or liver transplantation in the group receiving UDCA.[55] Thus the role of UDCA in CF remains unclear.

In the CF population, for which nutrition already remains an important focus of care, the development of liver disease exacerbates this issue. It has been recommended that individuals with CF receive 150% of the recommended daily allowance (RDA) for calories by increasing dietary fat as opposed to carbohydrate supplements due to the risk of developing CF-related diabetes mellitus. The requirements of fat-soluble vitamins (A, D, E, and K) are also increased in CFLD and higher doses are often needed. Fat-soluble vitamin levels should be monitored closely and the doses adjusted accordingly. Pancreatic enzymes should be optimized to allow maximal absorption of long-chain triglycerides and essential fatty acids.[57]

Recognizing the development of portal hypertension is essential to the care of individuals with CFLD. Signs of this CFLD complication include splenomegaly, leucopenia, and thrombocytopenia. Reversal of, or abnormal, portal vein flow can be identified on liver Doppler ultrasound. Other complications associated with portal hypertension include variceal bleeding, low oxygen saturations due to hepatopulmonary syndrome, or abdominal distension due to ascites.

The greatest concern with portal hypertension is the life-threatening complication of variceal bleeding from either esophageal or gastric varices. An individual with an acute variceal bleed may present with hematemesis or passage of maroon-colored or melanotic stools. In children with portal hypertension, unlike in adults with portal hypertension, screening for the presence of varices is not recommended because there is no evidence-based therapy that is safe and effective to prevent the first variceal bleed (also known as primary variceal prophylaxis).[58] However, recent expert opinion has suggested that adult guidelines can be followed after puberty for variceal screening at the discretion of the treating physician.[59] Unfortunately, there is a paucity of literature in dealing with primary prophylaxis for varices in pediatrics; there are several case studies but only one randomized clinical trial. In one retrospective study of 38 children with CF and liver cirrhosis, variceal bleeding occurred in 50%; two of the children had exposure to salicylates prior to the bleed.[60] Thus salicylic acid and nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided to minimize the risk of bleeding from esophageal or gastric varices.[47]

Once a variceal bleed has occurred, the child is at high risk of recurrence of bleeding. The prevention of a second bleeding episode is called secondary prophylaxis. In adults the preferred method for secondary prophylaxis is the use of a long-term nonselective β blocker with serial endoscopic variceal ligation (EVL) until the obliteration of the varices is complete.[61] The use of a nonselective β blocker has not been adequately studied in children for secondary prophylaxis. Furthermore, the pulmonary side effects of nonselective β blockers would most likely preclude their use in children with CF. Thus EVL is the preferred method of secondary prophylaxis in pediatrics.[58] EVL is not possible in infants weighing less than 12 kg due to the size of the equipment needed for EVL, so endoscopic sclerotherapy is used as secondary prophylaxis in these patients.

Gastric varices tend to be technically more difficult to address in pediatrics than in adults. In the adult literature, EVL can be performed with gastric varices that extend onto the cardia on the lesser curvature of the stomach.[62] Injection of cyanoacrylate glue is another option for treatment of gastric varices.[63] In children with difficult to control gastric varices or recurrent variceal bleeding, caregivers may consider the options of surgical portosystemic shunt or bypass procedure, transjugular intrahepatic portosystemic shunt (TIPS), or liver transplantation. Hepatic encephalopathy has occurred after portosystemic shunting; treatment includes lactulose and nonabsorbable antibiotics.

The decision on when to proceed with liver transplantation in the CF population has been controversial. Proposed indications include progressive hepatic dysfunction (decreasing albumin level and coagulopathy not correctable with vitamin K), development of ascites or jaundice, variceal bleeding not amenable to standard therapy, hepatopulmonary syndrome, unresponsive severe malnutrition, deteriorating quality of life, and deteriorating pulmonary function (Tiffeneau-Pinelli index $FEV_1/FVC < 50\%$).[47] Relative contraindications to liver transplant include colonization with multidrug resistant *P. aeruginosa* or *Burkholderia cepacia* due to the high risk of postoperative infection, which may be lethal.[64] The database for the United Network for Organ Sharing (UNOS) showed that 148 children with CF underwent liver transplantation alone, with a 5-year unadjusted survival of 86%. In an adjusted analysis the CF liver transplant recipients had inferior survival rates in long-term follow-up as compared with recipients with other indications for liver transplantation.[65] A higher incidence of anastomotic biliary strictures requiring creation of a Roux-en-Y portoenterostomy has been reported in CF liver transplant recipients, possibly due to their underlying CF-related bile duct disease.[66] Most of the CF liver transplant recipients will develop diabetes, but 60% of untransplanted individuals with CF-related portal hypertension will develop diabetes as well.[67] Other than the development of diabetes, CF liver transplant recipients do not have increased mortality from other complications from CF (pulmonary failure, infections).[68] Some advocate for isolated liver transplantation prior to deterioration of lung function because combined liver-lung transplantation carries a worse prognosis.[69] However, it has been reported that outcomes for isolated liver transplantation and combined liver-lung transplantation in CF recipients are comparable.[64]

# Gallbladder Disease

Gallstones occur in approximately 15%–30% of individuals with CF. These affected individuals are more likely to carry at least one Gilbert syndrome–associated UGT1A1 mutation which results in increased levels of unconjugated bilirubin.[70] This unconjugated bilirubin combines with calcium, which results in the calcium bilirubinate stones that are found in individuals with CF.[71] Unfortunately, these stones do not respond to UDCA. Thus cholecystectomy is considered in symptomatic individuals with cholelithiasis. Elevation in GGT and conjugated bilirubin with right upper quadrant abdominal pain should prompt urgent evaluation for gallstones.

Microgallbladder has been found in approximately 30% of individuals with CF on autopsy.[72] Some have proposed that this is the result of atresia or stenosis of the cystic duct.[73] In general, no treatment is required for microgallbladder.

# Infertility

In addition to the airway and digestive tract, CFTR is found in the male and female reproductive tract. CFTR mutations have been associated with congenital bilateral absence of the vas deferens (CBAVD) and congenital absence of the uterus and vagina (CAUV), suggesting that CFTR may play a role in the development of both the female and male embryogenic reproductive tracts.[74] In men with CF, 98% are infertile.[75] Typically, infertility is due to obstructive azoospermia.[76] However, less than 2% of men with CF will remain fertile, especially those with a class V CFTR mutation.[77] Sperm harvest techniques including microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), and testicular sperm aspiration are possible options for treatment. Although the number of pregnancies after these procedures is small, the outcomes are similar to those in men without CF.[74]

In contrast, approximately 50% of women with CF are able to conceive a child naturally.[78] Typically, the reproductive anatomy for females with CF is normal. Even with a normal cervix, the abnormal CFTR function leads to thickened and dehydrated tenacious cervical mucus that interferes with cervical penetration by sperm.[78] Menarche is delayed in females with CF by almost 2 years on average regardless of nutritional status, especially among those with abnormal oral glucose tolerance test (OGTT) and those who are homozygous for ΔF508.[79] Treatment involves medication like clomiphene citrate to help stimulate ovulation, intrauterine insemination (IUI), *in vitro* fertilization (IVF), or intracytoplasmic sperm injection (ICSI) in more complicated cases.[74]

## Cystic Fibrosis Transmembrane Conductance Regulator Actions in the Small Bowel

Typical gastrointestinal (GI) physiology follows the entrance of acid pH chyme from the stomach into the duodenum, triggering a host of gut hormone release from the duodenum that has an effect on the pancreas and duodenal cells to secrete bicarbonate and stimulates release of pancreatic enzymes in the zymogen form. Those enzymes are converted into a functioning form when contact is made with activating enzymes on the bowel luminal surface followed by a self-activation cascade. These pancreatic enzymes work optimally in a neutral pH environment and aid in the breakdown of protein and fat into digestible components. The gut hormone release from the duodenum also stimulates the gallbladder to excrete bile that begins the emulsification of lipids thus activating fat digestion. There are still other brush border enzymes that aid in carbohydrate metabolism and also work best in a neutral pH environment. CFTR is found on the apical surface of the intestinal crypts and villi and, in the pancreas, contributes to the release of bicarbonate into the bowel lumen. Without proper function of this protein channel there is an impaired bicarbonate secretion that results in a duodenal pH that is 1–2 units lower in CF patients than in healthy controls.[80] This more acidic pH has an adverse effect on the pancreatic enzyme function, micelle formation, and brush border enzyme function, thus affecting the digestion of all macronutrients.[80–82] The use of ivacaftor, the CFTR potentiator, has been shown to normalize the buffering capacity in patients with the G551D CFTR mutation.[80,81] Fluid secretion into the small bowel also appears linked to bicarbonate secretion via CFTR.[80]

## Meconium Ileus

MI is nearly pathognomonic for CF, although there can be other clinical causes. MI is one of the earliest signs of CF and occurs in 15%–20% of the CF population.[83,84] The occurrence of MI has been linked to CFTR gene mutations and thus clinical severity, which together can be used to further delineate CF phenotypes. Those with class I, II, or III mutations, in that order, are more likely to present with MI.[83] Nearly half the patients that present with MI will have at least one additional GI complication that could include ileal atresia, intestinal volvulus, bowel necrosis, bowel perforation with meconium peritonitis, or giant meconium pseudocyst; any of these additional complications confer the designation of a complicated MI case[84] (Fig. 52.4).

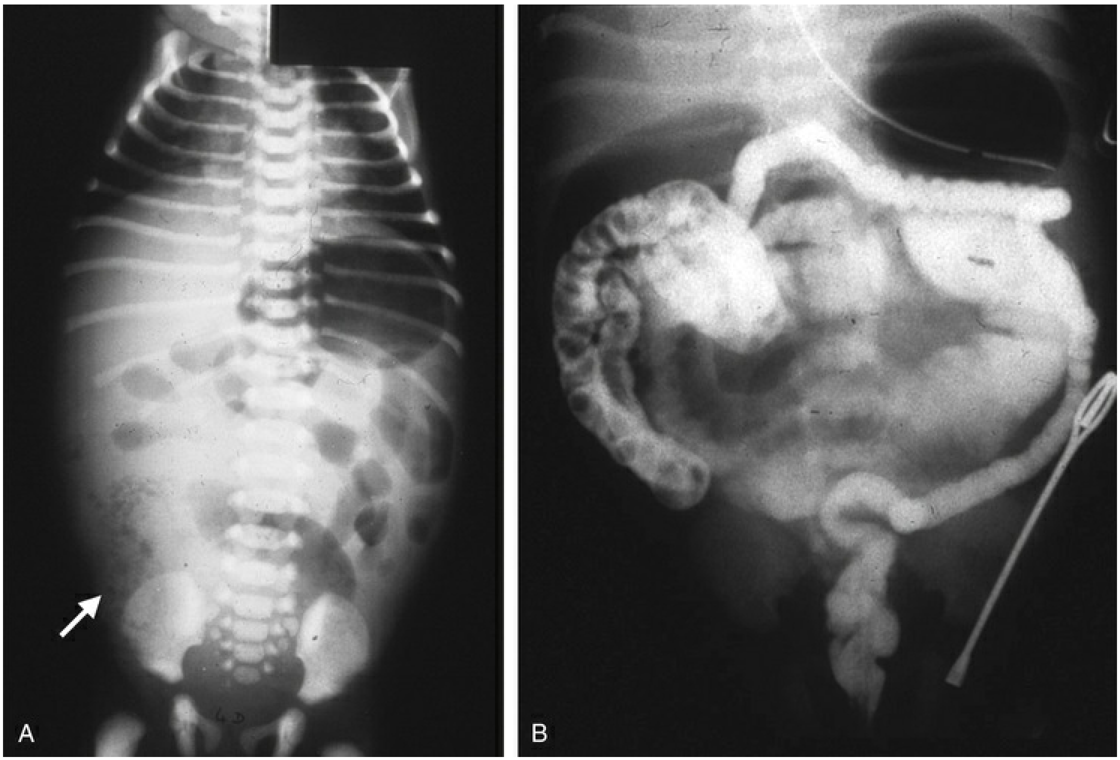

**FIG. 52.4** Meconium ileus. (A) Abdominal x-ray showing air-fluid levels in the small bowel and granular

material in the right lower quadrant with an absence of air in the colon. (B) Barium enema showing the presence of inspissated material in the small bowel and a microcolon.

Nonoperative management of MI can include the use of a water-soluble radiopaque solution (Gastrografin) that hydrates and softens the meconium mass when used via careful rectal instillation. While being therapeutic, it can also help to define the extent of the ileus and the size of the colon (often a microcolon). The goal of a Gastrografin enema is to have the solution reflux into the terminal ileum to relieve the obstruction. The Gastrografin also allows for observation of the bowel movements and can be repeated every 12–24 hours.[84] Other enema solutions that can be considered as supplementation to Gastrografin include warm saline with 1% *N*-acetylcysteine. The risks of hypertonic enemas can include severe bowel distention with perforation, hypovolemic shock due to fluid shifting, and bowel ischemia from overdistention and hypoperfusion.[84,85] These potential complications can be anticipated and require monitoring and rapid response to the fluid needs of the neonate. Success rates of nonsurgical management for simple MI have typically been reported near 80%, although more recent review of the literature reports closer to 40% success, citing less aggressive enema management and lower osmolarity of enema solutions as the reason for a faster conversion to surgical management.[84,85] In using this approach the complication rates have also decreased.[85]

Operative management remains an option, although it is typically reserved for complicated MI or MI that has not been responsive to the nonoperative approach. Over the years there have been many different surgical approaches with and without enterostomies but most with a resection of part of the affected bowel along with some instillation of irrigants.[84] A strong effort to minimize the amount of bowel resected can help with clinical management in the postoperative period. Following surgery some providers continue to instill 4% *N*-acetylcysteine via an ileostomy to help solubilize any residual meconium. It is recommended that stomas be closed as soon as possible to help avoid further fluid and electrolyte disturbances.[84] Most patients undergoing surgical management of MI require nutritional supplementation with parenteral nutrition (PN) for a short period of time. The longevity of PN dependence will vary from patient to patient, and early use of enteral nutrition is encouraged. The enteral nutrition could be breast milk or routine infant formula, although some cases may require partially hydrolyzed or elemental formula supplementation depending on the amount of bowel resected and patient's response to enteral feeding. When enteral feeding is initiated, it is important to also begin the use of PERT and vitamins.[84] Early involvement of your local pediatric gastroenterologist and CF dieticians who can help guide through the finer aspects of nutritional management is advised.

## Constipation

Constipation is defined as a decreased frequency of bowel movements from one's baseline bowel habits with increased consistency (hardening) of the stool or pain with defecation with or without abdominal distention. This is a common problem among patients with CF and thought to be in part due to the increased viscosity of the fluid secreted in the GI tract. Defective CFTR leads to reduced chloride and fluid secretion into the bowel lumen while also upregulating the epithelial sodium channel (ENaC), leading to increased absorption of sodium and fluid from the luminal mucus.[86] Newer treatments with CFTR channel activators have shown some improvement of fluid secretion in the intestinal lumen as measured by a wet to dry ratio in mice.[87] Treatment of constipation can be achieved with medications to increase the osmolality of the chyme so as to effectively pull in more water and keep the stool soft. Other treatments that may sometimes be necessary include stimulant laxatives and colonic lavage if osmotic laxatives alone are not successful.

## Distal Intestinal Obstruction Syndrome

Inadequate hydration of the chyme/stool can lead to a unique issue in patients with CF known as DIOS in which the chyme of the small bowel is inspissated and thick enough to activate the ileal brake, effectively causing a partial or complete bowel obstruction at the transition of the small bowel to the colon. In 2010 the European Society for Paediatric Gastroenterology Hepatology and Nutrition (ESPGHAN) CF working group defined two distinct types of DIOS.[88] First, there is complete DIOS, which is a complete intestinal obstruction with confirmatory clinical or radiographic findings, fecal mass seen or felt in the ileocecal area, and abdominal pain or distention or both. Second, there is incomplete DIOS that has days of abdominal pain or distension with a fecal mass in the ileocecal area without clinical or radiographic signs of obstruction.[88]

In either complete or incomplete DIOS the clinical presentation of these patients includes an acute onset of abdominal pain, typically in the right lower quadrant, that can be mistaken for appendicitis by those unfamiliar with the care of CF patients. There is an estimated prevalence range for the occurrence of DIOS of 5–12 episodes per 1000 patients per year.[89] Munck and colleagues prospectively studied 102 patients (both pediatric and adults) with at least 1 episode of DIOS in 10 countries for 1.6 years and found a recurrence of DIOS in nine patients for a total of 112 episodes of DIOS recorded. Using a multivariate analysis they found some association with comorbid conditions including MI, PI, CF-related liver disease, CF-related diabetes, and *P. aeruginosa* colonization.[90]

## Distal Intestinal Obstruction Syndrome Management

DIOS is treated with the goal of moving the bowel contents forward through the colon. Often this involves the use of oral osmotic laxatives along with oral hydration. Oral lavage with polyethylene glycol is commonly used at a dose of 2 g/kg per day, with a maximum of 80–100 g/day.[89] Gastrografin administered orally or via enemas is another effective treatment, it is diluted to various concentrations depending on the age of the patient and the route of administration.[88,89,91] Aggressive management of constipation with appropriate hydration and optimization of pancreatic replacement therapy is thought to help minimize the occurrence of DIOS, although this remains anecdotal.[88–91] In extreme cases with persistent obstruction or ischemia surgical management may be necessary.

## Rectal Prolapse

Rectal prolapse occurs in 3.5% of patients with CF, and we also know that 3.6% of patients who have rectal prolapse will be found to have CF.[92] Rectal prolapse can occur at any age, although it is most common younger than 3 years of age and generally resolves spontaneously without need for surgical intervention. Management of constipation and adequate PERT may help to lessen the frequency of prolapse occurrences.

## Gastric Emptying and Small Bowel Motility

Gastric emptying studies have not been consistently abnormal in CF patients. Prolonged intestinal transit time has been shown in adult and pediatric patients with CF when compared with healthy controls by breath testing.[93,94] Orocecal transit time has been shown to be greater than 7 hours in 80% of the CF patients compared to 12% of the healthy controls with the velocity of small bowel transit slowing in the distal small bowel, using radiopaque markers and magnet-based motility tracking.[95,96]

## Small Intestine Bacterial Overgrowth

Delayed small bowel motility along with frequent administration of antibiotics, a high-fat/high-carbohydrate diet and use of acid suppression may predispose patients with CF to small intestinal bacterial overgrowth (SIBO). SIBO is described as one or more types of bacteria that have overgrown their “normal” amount within the small bowel. Symptoms can include increased gas and bloating, with or without abdominal distention, and sometimes diarrhea. In particular the use of low-dose azithromycin has been implicated in SIBO in the CF community.[97] Diagnosis for SIBO may be clinical, or for older patients the use of a hydrogen breath test or methane measurement could be diagnostic.[97,98] Consequences of SIBO include a further exacerbation of malabsorption of nutrients and micronutrients if diarrhea is present. There is a decreased association of SIBO in patients with CF if they are regularly using laxatives.[97] Treatment can include a therapeutic trial of oral antibiotics (metronidazole, rifaximin, or ciprofloxacin). In CF patients with an exacerbation and also diagnosed with SIBO via hydrogen-methane breath test, oral treatment with ciprofloxacin was far superior to intravenous treatment with ceftazidime and amikacin for the resolution of SIBO.[99] There was also significant improvement in fat digestion and absorption in the ciprofloxacin group during this treatment.[99]

## Microbiome

In the past several years there has been a focus on both the intestinal and respiratory microbiome of CF patients. The microbial colonization of both the respiratory and intestinal tracts occur early in the life of an infant and is likely influenced by many factors, such as mode of delivery, contact with environment, feeding practices, and early antibiotic exposure. Infants followed from birth to 3 years of age with regular interval evaluation of the GI and respiratory microbiota were monitored for onset of CF exacerbations and were found to have a significant decrease in normal GI flora consisting of *Bacteroides* and *Bifidobacterium* just prior to onset of CF pulmonary exacerbations.[100] There was also a suggestion that increased GI microbial diversity and breast feeding were protective against CF exacerbations,[100] although more studies will be needed to evaluate this further. There has also been demonstration of an early dysbiosis in the microbiota of CF patients linked to malabsorption of dietary fat that therefore selects for a proinflammatory GI microbiome.[101] The use of newer metagenomic sequencing and taxonomic profiling methods has led to a rapidly expanding field that is defining not only which bacteria are present but in what quantity and is starting to allow us to define relationships to the health of CF patients. We anticipate a swift application and expansion of these techniques in the years to come.

# GI Cancers

Although the underlying pathobiology of GI carcinogenesis in CF patients remains speculative, both adenocarcinoma of the small bowel and colon have been found to be prevalent in this population. An increase in GI cancer incidence in CF patients compared with the general population with an odds ratio of 6.5 has been described with most of these cancers occurring in the third decade of life.[102] Registry data assessed over a 10-year period found that in the nontransplanted group there was a predominance of small bowel, colon, and biliary cancers that were diagnosed at a mean age of 39 years, with the highest risk group being patients homozygous for the 508del mutation.[103] In the transplanted cohort, small bowel and colon cancers remained the bowel cancers of note.[103] Adenomatous polyps as a precursor of adenocarcinoma have been described in 30- to 39-year-old patients. Risk factors associated with the formation of polyps include: homozygosity for the 508del mutation, CFRD, being a male, and lung transplantation.[102–104] Indications for colonoscopy include persistent diarrhea, iron deficiency anemia, hematochezia, and abdominal pain. At this time there are no consensus guidelines for colonoscopy screening in the CF population, although we expect such guidelines to emerge in the next few years.

# Nutrition

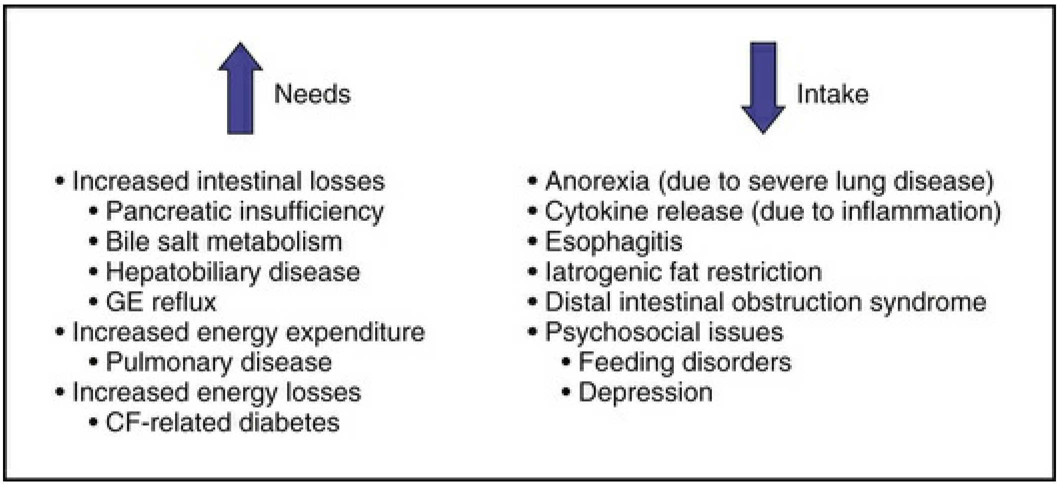
In the 1980s there were several published articles illustrating the link between nutritional status and CF pulmonary disease. One study demonstrated that increasing the caloric intake with night feeds stabilized pulmonary decline compared with standard of care.[105] Other studies linked improved nutrition with enhanced exercise performance.[106] One of the most convincing articles was a retrospective review at two respected CF centers that noted no difference in pulmonary treatment/care, but one of the centers had adopted an aggressive approach to the use of PERT and caloric intake in their patients and that resulted in significantly improved survival.[107,108] There have been several newer studies that have linked good nutritional status as measured by nutritional indices such as height growth, weight gain, and body mass index (BMI) early in life with improved survival and preserved pulmonary function.[109–112] Nutrition has become a major clinical focus in recent years. There is also an association of poor nutrition with decreased health related quality of life in children age 9–19 years.[113]

Given all these supporting data, several clinical nutrition guidelines have been published recently, including the European Society for Clinical Nutrition and Metabolism (ESPEN), European Society for Paediatric Gastroenterolgy Hepatology and Nutrition (ESPGHAN), and the European Cystic Fibrosis Society (ECFS) guidelines[114] and the clinical practice guidelines from the CF foundation.[115] These guidelines give structure to screening nutritional status and recommend obtaining height and weight at every visit so that a weight for length or BMI can be calculated. Goal weight for length, on the World Health Organization growth curves given the same age population, is the 50th percentile during the first 2 years of life.[114,115] From age 2–18 years on the Centers for Disease Control and Prevention growth curves, the BMI goal is 50th percentile of the same age population.[114,115] For adults greater than 18 years, the female goal for BMI is 22 kg/m$^2$ and for males 23 kg/m$^2$.[114]

Given these aforementioned BMI goals, the guidelines also focus on recommended caloric intake goals. It is estimated that an infant with CF has caloric needs closer to 150 kcal/kg than the standard of 100–120 kcal/kg.[116] Breast milk is still considered best for patients with CF because it offers colonization with mother's microbiome, passive antibody transmission for increased immunity, and nutrients that are easy to digest.[24,116] Although the concentration of breast milk can vary, it is rarely higher than 20 kcal/ounce. Some mothers can overcome the increased caloric intake needs by increased volume production. Otherwise, these needs can be met by increasing the caloric density of the feeds with supplementation or fortification of breast milk.[24,116] We would highly recommend breast-feeding unless the child is losing weight or failing to gain weight. After solid foods are introduced, the simultaneous introduction of high-calorie, high-fat foods will help to address the increased caloric need. Finding healthy ways to enrich foods with additional calories and fats is encouraged from an early age.[114–116]

Supplements of additional oils, especially medium chain fatty acids (no transport needed for absorption) are often started early.

The caloric goals of a toddler/preschool child with CF is closer to 90–110 kcal/kg per day, with a protein goal that increases from 13 g/day at ages 2–3 years to 19 g/day for children aged 4–5 years.[115] For older children and adults it is estimated that patients with CF require from 120% to 150% of the energy needs of a healthy population (Fig. 52.5).[114]



Needs
Intake
• Increased intestinal losses
• Pancreatic insufficiency
• Bile salt metabolism
• Hepatobiliary disease
• GE reflux
• Increased energy expenditure
• Pulmonary disease
• Increased energy losses
• CF-related diabetes
• Anorexia (due to severe lung disease)
• Cytokine release (due to inflammation)
• Esophagitis
• Iatrogenic fat restriction
• Distal intestinal obstruction syndrome
• Psychosocial issues
• Feeding disorders
• Depression

**FIG. 52.5** Model for the development of energy imbalance in cystic fibrosis.

Consuming adequate calories for a patient with CF can be difficult given their increased needs due to malabsorption, along with chronic and recurrent infections, and exacerbations. If patients are having difficulty gaining weight, optimization of PERT and consideration of acid suppression to enhance PERT efficacy should be considered.[112,114,115] Other therapies to consider include promotility agents and appetite stimulants.[112] Dietary supplements should be considered, although the evidence for this remains low and there is a strong recommendation to individualize care in this arena; there may be need for behavioral interventions as well.[114] If there is a continued struggle to gain weight, care providers may need to consider tube feedings via nasogastric tubes (NGTs) or gastrostomy tubes (G-tubes), to provide nutritional supplements either during the day or at night.[114,115] The preschool guidelines offer algorithms to consider when analyzing the utility of G-tubes.[115] PN is not generally recommended except for specific cases where enteral feedings are not possible.[114]

Another aspect of nutrition involves the micronutrient requirements of CF patients. These markers of nutritional status are monitored via biochemical or laboratory measurements of serum or plasma. The general recommendation is to obtain these markers yearly for screening and more frequently if abnormalities arise and adjustments are being made.[114–117] The recommended markers include a red blood cell count, iron status, fat-soluble vitamin levels, electrolyte levels, zinc, transaminases (AST/ALT), biliary tree measurements (bilirubin and GGT) and "liver function tests."[114,115] There are some special circumstances when $B_{12}$, folic acid, vitamin C, or selenium are monitored, but these are not routinely recommended. Patients with CF are at increased risk of some micronutrient deficiencies; in particular they are at risk of fat-soluble vitamin deficiencies given the higher rates of fat malabsorption in patients who are pancreatic insufficient. Specific fat-soluble vitamin formulations are available commercially and are typically used to supplement the fat-soluble vitamin intake, although there are times when individual vitamin supplementation should be considered, especially if there are specific deficiencies (Table 52.1).

## Table 52.1
## Fat-Soluble Vitamins

| | **Pathophysiology** | **What to Measure** | **Signs of Deficiency** | **How to Treat Deficiency** |
|---|---|---|---|---|
| Vitamin A | Cofactor in pathways for vision, growth and immune development and regulation | Serum vitamin A level | Night blindness | Oral supplementation **can have toxicity |
| Vitamin D | Bone/calcium homeostasis | 25-OH vitamin D | Osteoporosis is a late finding but can be monitored with DEXA scans | Oral supplementation with cholecalciferol and weight-bearing exercise |
| Vitamin E | Antioxidant throughout the body | α-tocopherol/cholesterol ratio or total serum lipid ratio | Peripheral neuropathy with loss of reflexes or hemolytic | Oral supplementation |

| | | | | |
|---|---|---|---|---|
| | | | anemia | |
| Vitamin K | Cofactor for many proteins in the clotting cascade | PT/INR | Coagulopathy with a prolonged PT/INR | Oral, IV, or IM supplementation |

*DEXA*, Dual-energy x-ray absorptiometry; *IM*, intramuscular; *IV*, intravenous.

Zinc and sodium are other micronutrients that also require monitoring in CF patients.[24,112,114,115] Zinc is an enzymatic cofactor used in many growth and immune function pathways. Measurement of a serum zinc level can be followed over time. Clinical symptoms of deficiency include diarrhea, dermatitis, and poor weight gain. Oral zinc supplements can be used to replace stores. Sodium is a cation that is prevalent in the extracellular fluid and is used in many regulatory processes throughout the body. It is measured routinely as a serum electrolyte, and patients with CF are at an increased risk of depletion due to their excessive salt loss through the skin. Higher dietary requirements or supplements may need to be considered especially in summer months or early in life when growth is rapid.[24,112]

## Cystic Fibrosis–Related Diabetes

CFRD has an age-dependent incidence that ranges from 5% in 10–14 year olds to 13% in 15–19 year olds and near to 50% in patients 30–50 years of age.[118] The pathophysiology of CFRD appears quite complex, with multiple possible contributors. It has characteristics of both type I and type II diabetes but is in fact a unique type. Exocrine pancreas destruction from chronic pancreatitis with progressive fibrosis leading to islet disruption and loss of alpha and beta cells is the generally accepted explanation.[118,119] Therefore insulin insufficiency, as in type I diabetes, is the main contributor to the pathophysiology, although there is some thought that a fluctuating level of insulin resistance is also contributing to the pathophysiology. The insulin resistance may work through other factors including autoantibodies, inflammation, infection, malnutrition, genetic susceptibility, and impaired insulin sensitivity.[118,119] The use of A1C testing in not recommended for CFRD, instead early detection is reliant on an OGTT.[118–120] It is recommended that annual screening is started with an OGTT at age

10 years.[118–120] There are also recommendations to monitor patients receiving antibiotics, glucocorticoids, and enteral tube feedings and to monitor women prior to, during, and post pregnancy.[120] Medical nutrition therapy with a reduction in carbohydrate load and insulin are the mainstays of treatment.[118–120] According to a recent Cochrane review, there is no advantage to using oral hypoglycemic agents compared with insulin in CFRD.[121] There are current clinical care guidelines for CFRD that address the specifics of diagnosis, treatment, and management.[120]

# Conclusion

There has been substantial advancement in the knowledge of CFTR function outside the pulmonary system and its relation to disease manifestations and progression. This has led to a rapid expansion of necessary care team members on both the pediatric and adult side, including specialists in gastroenterology, endocrinology, fertility, and women's health. The role of CFTR corrector and potentiator therapies is just starting to be addressed in these other organ systems, which will continue to lead to a better overall understanding of pathophysiology related to CFTR.

## Introduction

The impressive improvement in life expectancy in cystic fibrosis (CF) over recent decades has been achieved by treatments that are aimed at the downstream consequences of absent or dysfunctional CF transmembrane conductance regulator (CFTR) activity (including aggressive treatment of infection, airway clearance and nutrition) rather than by targeting CFTR directly. In contrast, novel approaches using CFTR modulators or gene therapy aim to target the root cause of the disease, replacing/repairing the CFTR gene or addressing the underlying defects responsible for defective CFTR channel function, intracellular processing, or production. Ultimately, the aim is to fully correct the defective CFTR and restore normal function. There is already some evidence that CFTR modulation can affect the disease trajectory in CF.[1]

This chapter describes the therapeutic strategies for CF which are based on targeting CFTR, either at the gene or protein level. We will provide updates on small molecule CFTR modulators and gene therapy, focusing on clinical development and evaluation. The challenge for the field is to find drugs or combinations of drugs capable of restoring CFTR function, applicable to patients with any genetic mutation.

## Small Molecule Cystic Fibrosis Transmembrane Conductance Regulator Modulators

The focus of this section is on CFTR modulators licensed for clinical use or in clinical trials at the time of writing. The wave of CFTR modulators currently in the initial stages of development or under evaluation in clinical trials will inevitably mean that for the reader to remain up to date, information in this chapter will need to be reviewed in conjunction with new evidence as it becomes available. Table 53.1 lists the drugs targeting CFTR, which are at clinical stages of testing. Clinical trials are registered on the US National Institutes of Health ClinicalTrials.gov website (https://clinicaltrials.gov/). The US Cystic Fibrosis Foundation also has an interactive drug development pipeline on its website that takes the reader to an overview of evidence to date from clinical trials and trials currently in progress (https://www.cff.org/Trials/Pipeline).

**Table 53.1**

**New Drugs in the Therapeutic Pipeline**

| Class of Drug | Agents | Current Status |
|---|---|---|
| Gene replacement therapy | pGM169/GL67A (UK CF Gene Therapy Consortium) | Primary end point met in phase IIb clinical trial (59) |
| mRNA repair | QR-010 (ProQR Therapeutics) | Trials of nasal delivery and nebulization underway |
| Read-through agents | Ataluren (PTC124; PTC Therapeutics) | Recent announcement of 2nd phase III trial failure http://ir.ptcbio.com/releasedetail.cfm?releaseid=1015471 |
| Amplifier | PTI-428 (Proteostasis Therapeutics Inc) | Early-phase trials of oral agent underway |
| Correctors (+/ −potentiator) | Lumacaftor/ivacaftor (Orkambi, Vertex) | Licensed for F508del homozygous patients |
| | Tezacaftor (VX661)/ivacaftor (Kalydeco; Vertex) | Phase III program in F508del homozygous and heterozygous patients underway |

|  |  |  |
|---|---|---|
|  | Next-generation triple component drugs (Vertex) | Early-phase trials underway with several agents administered with 661/ivacaftor |
|  | Riociguat (Bayer) | Phase II trial underway |
|  | GLPG2222 and GLPG2737 (Galapagos) | Early-phase trials underway |
|  | FDL169 (Flatley Discovery Labs) | Phase II trial to commence 2017 |
| Potentiator | Ivacaftor (Kalydeco; Vertex) | Licensed for patients with gating mutations aged 2 years and older and R117H<br>A component of all Vertex's combination drugs |
|  | GLPG1837 (Galapagos) | Phase II trial data awaited |
|  | QBW251 (Novartis) | Phase II study results awaited |
|  | GLPG2451 (Galapagos) | Early-phase trials as mono and in combination with GLPG2222 |
|  | GLPG3067 (Galapagos) | In phase I trial |
|  | Deuterated ivacaftor (CTP-656, Concert) | In phase II trial of patients with gating mutations |
| Stabilizer | Cavosonstat (N91115; Nivalis Therapeutics) | Recent announcement of failed phase II trial http://ir.nivalis.com/press-releases/detail/60 |
| ENaC inhibitor | VX-371 (Vertex) | In phase II trial in patients on Orkambi (also being tested in primary ciliary dyskinesia [PCD]) |

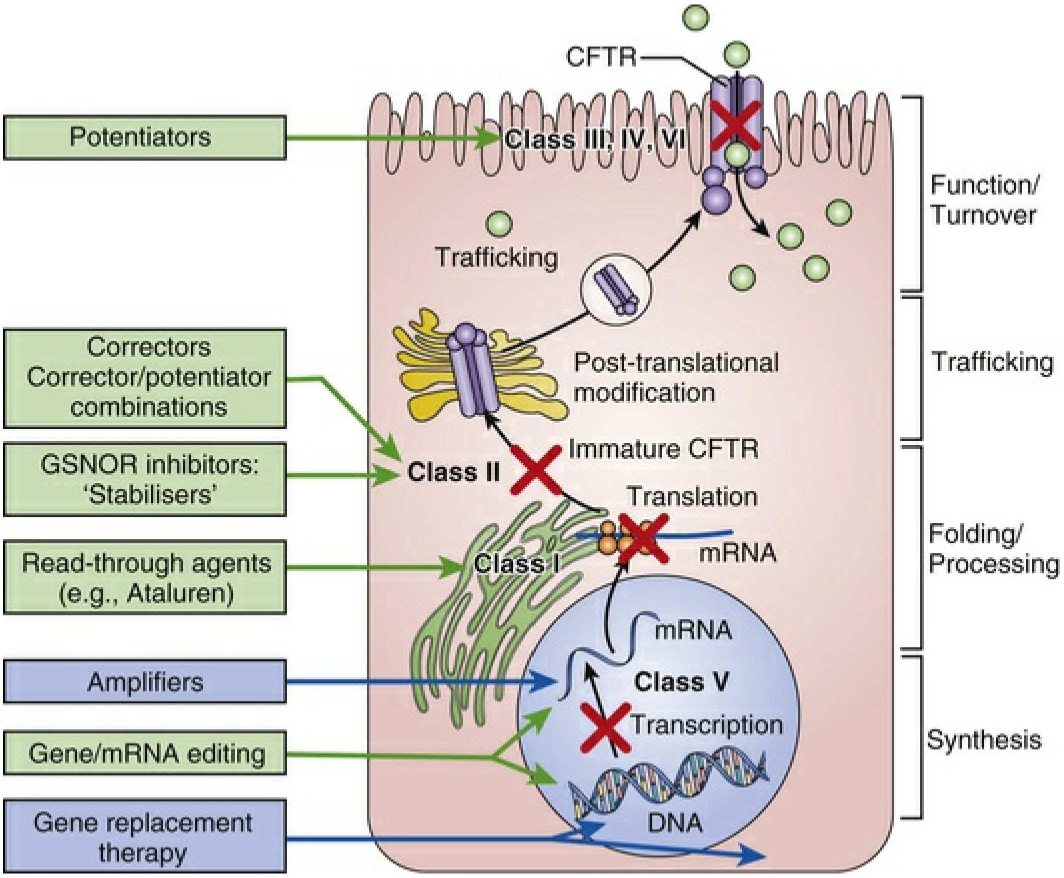
## Identifying Candidate Drugs

Drug development typically starts with identification of a therapeutic target, which may be site-, cell-, or receptor-specific. Candidate compounds are then investigated for their ability to modulate this target. These can be either selectively or randomly chosen; the latter clearly requires high-throughput screening techniques—automated assays that allow high numbers of potential compounds to be screened quickly. "Lead" compounds showing potential undergo further preclinical assessment (further information at http://www.cftr.info/drug-research-development/pre-clinical-development/pre-clinical-validation-of-cftr-therapies/). Optimization to improve selectivity of the desired target, pharmacokinetics, and preclinical toxicology follows. The agents that are considered promising at the end of this process may proceed to clinical trials. Both traditional and high-throughput screening processes have been used to identify potential compounds that target defective or absent CFTR. Understanding functional manifestations at the protein/molecular level of a particular disease-causing mutation in CF allows the use of assays in high-throughput screening that can identify any impact on CFTR function (e.g., assays measuring anion conductance across cell membranes act as a "readout" for CFTR function).

## Impact of Cystic Fibrosis Transmembrane Conductance Regulator Mutations on Protein Expression, Maturation, or Function

A basic understanding of CFTR structure and function is important to understand the rationale for CFTR modulators. CFTR is a 1480–amino acid protein belonging to the adenine nucleotide binding cassette (ABC) transporter superfamily, expressed at the apical membrane of specialized epithelial cells.[2] It has multiple functions, but its role as a chloride and bicarbonate transporter is best characterized.[3] A detailed description of the consequences of absent or dysfunctional CFTR in CF is described in Chapter 49.

More than 2000 mutations in the *CFTR* gene have been identified (http://cftr2.org), although the number determined as definitely disease causing is currently less than 200. The single residue deletion of phenylalanine at codon 508 (Phe508del) is the commonest mutation globally, present in almost 90% of CF alleles. Of the remaining mutations, 159 occur at a prevalence >0.01% in the CF population.[4] Six main classes of CFTR mutation have been defined, categorized according to effects on CFTR production, intracellular processing, and function (Fig. 53.1).



CFTR
Potentiators
Class III, IV, VI
Function/ Turnover
Trafficking

Amplifiers
Class V
Transcription
Gene/mRNA editing
Synthesis
DNA
Gene replacement therapy

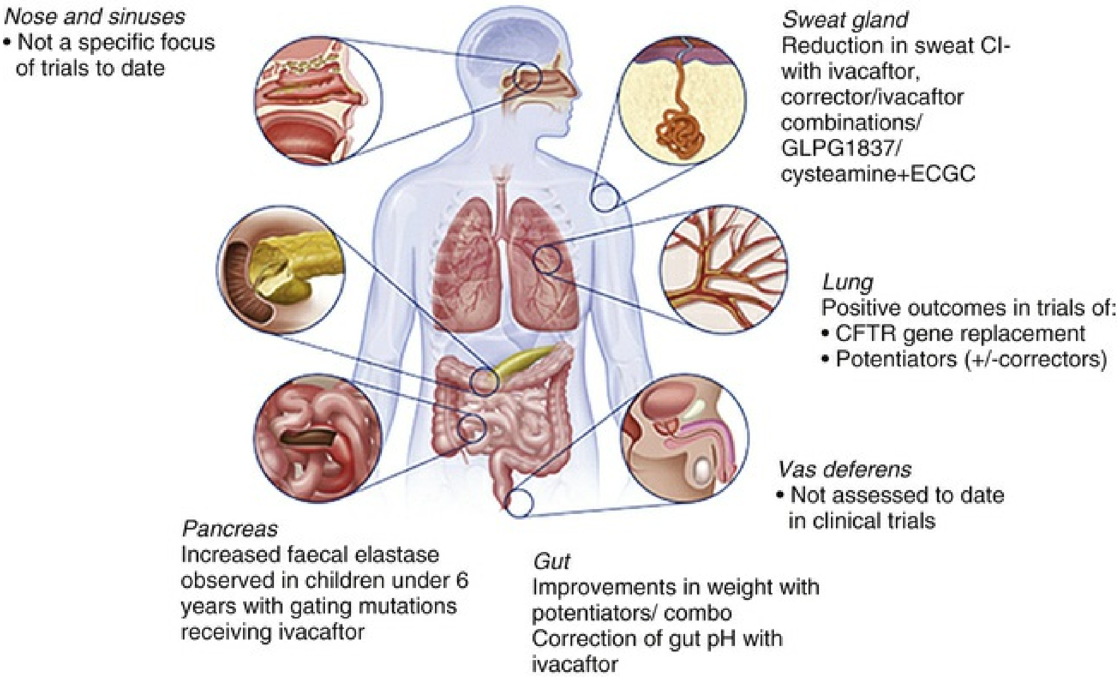
**FIG. 53.1** The many mutations in CFTR can be broadly grouped into classes depending on the effect the mutation has on the CFTR protein. Many drugs are being developed that target specific classes or individual mutations (examples shown in *green*), whereas other approaches could be considered mutation agnostic *(blue).* Reused with permission from www.cftrscience.com. *CFTR,* Cystic fibrosis transmembrane conductance regulator; *GSNOR,* S-nitrosoglutathione reductase; *mRNA,* messenger ribonucleic acid.

In class I mutations, a premature termination codon prevents full-length CFTR protein from being produced; these are present in approximately 10% of CF patients worldwide, although they are very much more common in certain populations such as the Ashkenazi Jewish population. Class II mutations (Phe508del being the commonest) result in CFTR being misfolded within the epithelial cell. As a result the protein cannot be transported to its site of action in the cell membrane, instead being prematurely degraded by the ubiquitin-proteasome system. In class III mutations, CFTR is produced and sited within the cell membrane, but there is infrequent opening (“gating”) of the chloride ion channel; these mutations are present in approximately 5% of CF patients worldwide, with the commonest by far being Gly551Asp (G551D). Class IV mutations (e.g., Arg117His) result in reduced ion conductance. Class V are splicing mutations, which result in reduced protein expression, and class VI mutations impact the turnover of CFTR at the cell membrane due to a reduced half-life. Despite these distinctions, it is important to recognize that the functional impact of the mutation may traverse several classes; for example, Phe508del (predominantly considered to be a class II mutation) also impacts the function of any CFTR that does reach the cell membrane (such as abnormal gating and reduced half-life).[5,6]

## Targeting Cystic Fibrosis Transmembrane Conductance Regulator Protein With Small Molecule Drugs

The small molecule drugs that target CFTR dysfunction are commonly referred to according to their mechanism of action. They include ribosomal read-through agents, “potentiators,” and “correctors.” Agents capable of “reading-through” a prematurely placed stop codon aim to produce a full-length functional protein. Potentiators are aptly named as they potentiate CFTR function but rely on appropriate placement within the cell membrane in the first instance. Correctors aim to rectify protein misfolding and thereby facilitate trafficking to the cell membrane.

Therapeutic candidates using one or more of these approaches have been evaluated in clinical trials, and a small number have now progressed through licensing to the clinic. They tend to be administered via the enteral route (possible due to their low molecular weight), which means multiorgan effects may be achieved (Fig. 53.2), and once commenced, the duration of treatment is potentially lifelong.



*Nose and sinuses*
• Not a specific focus of trials to date
*Sweat gland*
Reduction in sweat Cl- with ivacaftor, corrector/ivacaftor combinations/ GLPG1837/ cysteamine+ECGC
*Lung*
Positive outcomes in trials of:
• CFTR gene replacement
• Potentiators (+/-correctors)
*Vas deferens*
• Not assessed to date in clinical trials
*Pancreas*
Increased faecal elastase observed in children under 6 years with gating mutations receiving ivacaftor
*Gut*
Improvements in weight with potentiators/ combo
Correction of gut pH with ivacaftor

# Read-Through Agents

Stop codons are nucleotide triplets in messenger RNA (mRNA) that serve a key role in signaling the end of protein coding sequences (e.g., UAG, UAA, UGA). Premature stop codons are those that occur within the normal coding sequence due to a mutation. This means that the message to create the protein of interest is incomplete; thus only truncated protein is formed. Molecules that allow the read-through of premature stop codons, thus enabling the production of full-length protein, are being evaluated for several diseases including class I mutation CF.

The aminoglycoside gentamicin was initially shown to possess such capabilities,[7] but concerns over the adverse safety profile of this group of agents (renal toxicity and sensorineural deafness) led to a search for other potential candidates. The one that has been most extensively investigated is the oral small molecule drug ataluren (Translarna, formerly PTC124. PTC Therapeutics;

http://www.ptcbio.com/en/pipeline/ataluren-translarna/). This was identified by a high-throughput screening process involving more than 800,000 compounds. In *CFTR* knockout mice expressing human G542X mutant *CFTR*, ataluren increased CFTR expression at the apical surface of epithelial cells and restored cyclic adenosine monophosphate (cAMP)-stimulated chloride currents to approximately 25% of wild type.[8] Ataluren has been evaluated in both adults and children older than 6 years with at least one CFTR nonsense mutation. Changes toward normal in nasal potential difference (nPD) measurements (a bioelectrical test of CFTR function) were observed in most adults[9] and in approximately half of children in early phase trials.[10] An increased proportion of airway epithelial cells expressing CFTR detected by immunofluorescence was also seen.[10] These phase II trials involved CF patients from Israel (adults) and Europe (children). The results were in contrast to the lack of efficacy seen in a phase II trial of PTC124 in the United States.[11] The phase III randomized controlled trial (RCT) that followed involved 238 patients with a nonsense CFTR mutation. Patients were randomized to receive ataluren in a 3 times daily dosing regimen (10 mg/kg morning and midday; 20 mg/kg evening) or placebo for 48 weeks.[12] Although neither the primary outcome of forced expiratory volume in one second ($FEV_1$) nor the secondary outcome of a reduction in pulmonary exacerbations were met, on *post hoc* analysis these outcomes were statistically significant for patients who were not receiving concurrent inhaled tobramycin as part of their routine CF management.[12] This has led to a further phase III trial (NCT02139306) specifically for patients not on inhaled aminoglycosides, as it has been suggested that the lack of response in patients receiving aminoglycosides may be due to competition with ataluren at the ribosomal binding site; at the time of writing, the results of this second trial have not been published, but a sponsor's press release describes it as having failed to achieve its outcomes (http://ir.ptcbio.com/releasedetail.cfm?releaseid=1015471). Drugs such as ataluren targeting premature stop codons have the potential for broader applicability than being limited to a single disease. For example, ataluren has been granted a conditional marketing authorization by the European Medicines

Agency, based on the results of a phase IIb study in boys with Duchenne muscular dystrophy in conjunction with an unmet need for disease-modifying therapies in this condition.[13,14]

## Potentiators

The clinical trials of ivacaftor (Kalydeco, VX-770 Vertex Pharmaceuticals; http://www.kalydeco.com/how-kalydeco-works) undertaken to date have represented an important milestone in the proof of concept for drugs aiming to target the underlying molecular defect in CF. Identified through high-throughput screening, ivacaftor potentiated CFTR in human bronchial epithelial cells from compound heterozygotes with the commonest class III mutation Gly551Asp/Phe508del *in vitro*.[15] It was then evaluated in patients with at least one copy of this mutation; early-phase studies demonstrated evidence of functional improvement in CFTR with nPD and sweat chloride measurements. Phase III placebo controlled studies followed with impressive results. Efficacy was demonstrated on a regimen of ivacaftor 150 mg twice daily in adults and adolescents (STRIVE),[16] and children aged 6–11 years (ENVISION).[17] In both trials a significant improvement in lung function was seen on active treatment with absolute improvements in $FEV_1$ of 10.6% and 12.5%, respectively. The improvement in lung function was evident by week two of treatment with ivacaftor and was sustained through 48 weeks. In parallel, there were also significant reductions in sweat chloride concentrations, and improvements in quality of life and weight.[16,17] The pulmonary exacerbation frequency was significantly reduced in adults receiving ivacaftor.[16]

A key question for any therapy which can potentially affect the natural history of a disease course is whether efficacy can be demonstrated in patients with mild disease (i.e., before irreversible changes within the airway occur). The use of more sensitive outcome measures has helped to move this area forward in patients with normal lung function as assessed by $FEV_1$, the historically favored primary outcome. In patients with mild CF lung disease ($FEV_1 \geq 90\%$ predicted) aged 6 years and older with the Gly551Asp mutation, a clinical trial in patients demonstrated significant improvements in lung clearance index (LCI).[18] LCI has also been used to demonstrate efficacy in those with advanced disease ($FEV_1$ < 40% predicted).[19]

Following the clinical trial that demonstrated that improvement in LCI was observed in those with preexisting normal $FEV_1$, it became important to consider if the CFTR modulator ivacaftor could be given in the early years of life because CFTR modulation therapy might have the greatest potential to prevent organ damage at that stage. Outcome measures for lung efficacy are a challenge in this population, and therefore a clinical trial in preschool children was primarily undertaken using outcomes for safety and pharmacodynamics (sweat chloride). This open label study (KIWI) involved ivacaftor (50 mg or 75 mg twice daily) in preschool children with any *CFTR* gating mutation and found it was well-tolerated and safe, although an elevation in liver function tests (transaminases) warrants close monitoring in the clinic.[20] A notable finding in the KIWI study was the effects of ivacaftor on growth and pancreatic function. Increases in fecal elastase and decreases in serum immunoreactive trypsinogen on treatment were suggestive of partial improvement of exocrine pancreatic function. As a systemically administered therapy, small molecule CFTR modulators have the potential to affect nonpulmonary disease manifestations. At the time of writing, efficacy outcomes (LCI and computed tomography [CT] scans) are being further explored in a trial in 3–5 year olds (NCT02742519) and a trial in infants less than 24 months of age (NCT02725567) is assessing safety, pharmacokinetic, and pharmacodynamic outcomes.

Although initially restricted to patients with the commonest mutation in the class III group, *in vitro* evidence of efficacy in other *CFTR* gating and residual function mutations[15,21,22] led to the investigation of ivacaftor in non-Gly551Asp gating mutations and the Arg117His (R117H) class IV mutation. Efficacy was successfully demonstrated in non-Gly551Asp gating mutations in the KONNECTION study,[23] although for patients with Arg117His (KONDUCT),[24] efficacy was limited to patients older than 18 year. The authors suggested that ivacaftor may therefore be beneficial for patients with the Arg117His mutation who have established CF disease. The lack of effect in children may reflect the inclusion of this mutation in many CF newborn screen testing algorithms and its known phenotypic variability with milder variants being detected and thus skewing the population included in such clinical trials.

Key to the success of CFTR modulation is in the ability to alter the disease trajectory in CF. There is already some evidence that ivacaftor can achieve this,[1] and as the proportion of patients for whom this drug becomes part of routine CF care increases (in terms of mutation class and younger age), long-term pharmacovigilance will be eagerly awaited. The open label extension study of patients enrolled in the STRIVE and ENVISION trials (PERSIST; NCT01117012) reported absolute change in $FEV_1$ at week 96 (i.e., total duration of ivacaftor 144 weeks) of 9.4% and 10.3% in adults/adolescents and children, respectively, in those receiving ivacaftor in the original phase III trials.[25] A longitudinal study of ivacaftor in the postapproval setting reported improvements in several clinically relevant markers, including lung function, body mass index, mucociliary clearance, hospitalization rate, and *Pseudomonas aeruginosa* burden.[26]

The successes of the ivacaftor clinical trials have sparked heightened interest in the search for more efficacious CFTR potentiators. Several companies are conducting early-phase clinical trials at the time of writing. This includes Galapagos NV with GLPG1837[27] in patients with the Gly551Asp mutation (NCT02707562) and the S1251N gating mutation (NCT02690519), as well as two other molecules. Novartis Pharmaceuticals have undertaken a trial of their CFTR potentiator, QBW251, in patients with CF (NCT02190604).[28]

Concert Pharmaceuticals, Inc. have conducted a phase I trial of deuterated ivacaftor. Their strategy is based on selectively replacing hydrogen atoms with deuterium (a heavy isotope of hydrogen), with the aim of stabilizing carbon bonds within a compound. Their deuterium-modified ivacaftor (CTP-656) had a superior pharmacokinetic profile to standard ivacaftor (Kalydeco) in healthy volunteers.[29]

As a single agent therapy, the patients benefiting from potentiator therapies are limited to a minority of the CF population with class III and IV mutations. In patients with the class II mutation Phe508del, the *in vitro* data suggesting small potentiating effects of ivacaftor in bronchial epithelial cells from Phe508del homozygotes[15,30] did not translate into clinically detectable benefit.[31] Strategies for tackling Phe508del are discussed in the next section.

## Correctors

Drugs that target class II mutations in CF (e.g., Phe508del) in which a misfolding of CFTR leads to failure of its trafficking to the apical cell membrane are referred to as *correctors*. Because this class of mutations represents the greatest proportion of mutations within the CF population, an effective CFTR modulator in this group would have a profound impact. The furthest developed drug in this class is the oral small molecule drug lumacaftor (VX-809, Vertex Pharmaceuticals). *In vitro* studies demonstrated that in cell culture of bronchial epithelial cells homozygous for the Phe508del mutation, lumacaftor increased chloride secretion to approximately 14% of wild-type CFTR,[32] through its mechanism of action on the processing of CFTR in the endoplasmic reticulum. Functional evidence of efficacy as assessed by sweat chloride was demonstrated in adult CF patients homozygous for the Phe508del mutation, although these were small in magnitude and were not associated with significant clinical changes.[33] The single drug approach may be limited by the complexity required to restore CFTR function in patients with Phe508del.[34]

There are several other drugs being investigated that may have a novel mechanism of action in modulating CFTR. The nitric oxide pathway may be a possible CFTR corrector strategy (either via the direct or indirect pathways).[35] Examples in early-phase clinical trials include N91115 (Nivalis Therapeutics, Inc.), which the company describes as a first-in-class CFTR “stabilizer.” N91115 is an S-nitrosoglutathione reductase inhibitor. The aim is to stabilize CFTR both from within the cell and on the apical surface of the airway epithelial cells. Following a phase Ib clinical trial investigating N91115 monotherapy in adults homozygous for the phe508del mutation (NCT02227888), a phase II trial of safety and efficacy in patients receiving lumacaftor/ivacaftor (i.e., as a triple approach)

(NCT02589236) has recently completed. Most recently, Nivalis Therapeutics have commenced a further phase II trial of N91115 in adult patients heterozygous for F508del-CFTR and a gating mutation receiving ivacaftor treatment (NCT02724527); results have not been published in a peer-reviewed journal, but at the time of writing, the company's press release indicates a safe but ineffective drug (http://ir.nivalis.com/press-releases/detail/60). Also involving the nitric oxide pathway, the drug riociguat (BAY63-2521, Adempas, Bayer), with existing approval for the treatment of chronic thromboembolic pulmonary hypertension, has been found to have CFTR corrector function and is currently being investigated in a phase II study (NCT02170025) assessing safety, tolerability, and efficacy of the orally administered drug in adult patients homozygous for phe508del. Phosphodiesterase inhibitors including sildenafil, vardenafil, and tadalafil may also prove useful in CF caused by class II mutations. Using an inhaled preparation, these drugs have been shown to induce changes toward normality in nPD measurements in p.Phe508del mice,[36] but it has been suggested that high doses may preclude this as a therapeutic approach in humans.[37]

## Combination Therapy

Given the lack of clinical efficacy of lumacaftor alone in patients homozygous for Phe508del, the addition of a potentiator to maximize the function of any CFTR reaching the cell surface is an attractive option. Most research to date has been with the combination of ivacaftor and lumacaftor, the potentiator and corrector described in previous sections. *In vitro* studies showed that addition of ivacaftor to lumacaftor-exposed Phe508del homozygous cells further increased chloride transport to 25% of wild type,[32] in keeping with prior observations of defective gating in addition to defective processing of Phe508del CFTR.

Subsequently, two large phase III RCTs (TRAFFIC and TRANSPORT) studied patients aged 12 years and older homozygous for Phe508del. They showed relatively small but significant improvement in lung function of the magnitude of 3%–4% predicted $FEV_1$, on a regimen of lumacaftor (either 400 mg twice daily or 600 mg daily) and ivacaftor 250 mg twice daily.[38] More impressive was the reduction in the rate of pulmonary exacerbations (30%–39% reduction). Although the lumacaftor-ivacaftor was generally well tolerated, trial discontinuation was higher in the active arm, and the adverse events occurring more frequently in the active treatment group tended to be respiratory in nature (e.g., bronchospasm and dyspnea). The combination therapy lumacaftor-ivacaftor has now been licensed by the US Food and Drug Administration (FDA) (lumacaftor/ivacaftor, Orkambi, Vertex Pharmaceuticals, Inc.), and is available clinically in several countries, although reimbursement is not approved worldwide.

The magnitude of the improvement in lung function with ivacaftor and lumacaftor in Phe508del homozygotes was lower than that observed with ivacaftor in class III mutations.[38] *In vitro* assays on Phe508del human bronchial epithelial cells treated with lumacaftor/ivacaftor have shown that ivacaftor may be destabilizing CFTR that has been transported to the cell membrane by lumacaftor, and this may help to explain the relatively limited efficacy observed with this combination of drugs *in vivo* in clinical trials. This destabilization has been shown to cause a reduction of CFTR on the apical cell membrane and a reduced half-life resulting from increased turnover.[39,40]

As described for CFTR modulation with ivacaftor, one of the key aims is to be able to instigate therapy before irreversible changes resulting from CF lung disease occur. Therefore the tolerability, safety profile, and efficacy in children and those with mild disease are important. A phase III trial in younger children (6–11 years) to assess the impact of Orkambi in earlier disease (NCT02514473), using LCI as the primary outcome, is in progress.

Lumacaftor is the only CFTR corrector to have progressed to licensing (as the combination formulation); however, other candidates are being investigated. The corrector VX-661 in combination with ivacaftor (Vertex Pharmaceutical, Inc.) showed promising results in early-phase trials[41,42] and is currently undergoing evaluation in a number of large, phase III clinical trials in Phe508del homozygotes (NCT02347657) and Phe508del heterozygotes with a second mutation (1) which has been shown to be responsive to ivacaftor (NCT02412111), (2) with residual function (NCT02392234), and (3) likely unresponsive to VX661 or ivacaftor (NCT02516410). Following participation in these trials, patients may elect to roll over into a longer, open-label trial (NCT02565914). Interestingly the compound VX-661 does not appear to destabilize ivacaftor in the same way reported for the lumacaftor/ivacaftor combination and thus may be suited to the combination therapy approach.

Other companies are also developing drugs for a triple therapy approach with existing combinations of CFTR modulation. Proteostasis Therapeutics, Inc. have developed PTI-428 as a CFTR amplifier, which aims to increase an immature form of CFTR protein to provide additional substrate for other CFTR modulators. A safety and pharmacokinetic study involving adult patients with CF is being undertaken at the time of writing (NCT02718495). Flatley Discovery Labs have a combination of modulators from which encouraging *in vitro* data have recently been reported.[43]

Autophagy, a major mechanism used by cells in protein turnover within the cytoplasm, has been shown to be abnormal in CF cells with the F508del mutation related to depletion of the essential autophagy-related protein Beclin 1 (BECN1). A phase II trial of two proteostasis regulators (cysteamine and epigallocatechin gallate [EGCG]) for the autophagy-dependent rescue of CFTR reported improvements in sweat chloride, inflammatory markers, and $FEV_1$ in patients with Phe508del or other class II homozygotes or compound heterozygotes.[44,45] The authors reported that patients in this trial whose primary nasal brushed cells did not respond to cysteamine plus EGCG *in vitro* also exhibited deficient therapeutic responses *in vivo*.[45]

## Other Noncystic Fibrosis Transmembrane Conductance Regulator–Based Approaches

Small molecule drugs targeting the epithelial sodium channel ENaC are emerging as an active field of research. For example, Vertex Pharmaceuticals, Inc. have, at the time of writing, commenced a phase II clinical trial of a triple therapy approach with VX-371 (P-1037) in combination with Orkambi (NCT02709109) in patients aged 12 years and older homozygous for the F508del CFTR mutation.

## Cystic Fibrosis Gene Therapy

The successful development and licensing of Kalydeco and Orkambi have provided proof of concept that correction of CFTR function can improve CF. Gene therapy defined as the addition of *CFTR* DNA into cells, which is transcribed and translated into CFTR protein, has been developed since identification of the disease-causing gene more than 25 years ago, and important milestone studies are shown in Box 53.1. The combination of (1) CF being a single gene disorder, (2) the comparatively easy, noninvasive access to the lung, (3) the fact that gene therapy does not require detailed information about the patient's genotype or to which of the six mutation classes these might belong, and (4) lack of understanding of the disease pathophysiology led to unrealistic expectations by academia, industry, and patients in early phases of the program. It quickly became clear that CF gene therapy was considerably more challenging than initially anticipated. However, over the past two decades significant progress has been made, including identification of suitable gene transfer agents (GTAs), understanding limitations of molecular surrogate markers, and optimization of clinical trial design.

### Box 53.1

### Gene Therapy Milestone Studies

- Three years after cloning of *CFTR,* Rosenfeld et al. provided evidence of successful CFTR mRNA and protein expression after adenovirus-mediated *CFTR* cDNA transfer into cotton rats[95]
- Four years after cloning of *CFTR* Hyde et al. showed that nonviral *CFTR* cDNA transfer could partially correct the

chloride transport in tracheal epithelium of CF knockout mice[96]

- In the same year, Zabner et al. performed the first, albeit small and not placebo-controlled, CF gene therapy trial in three patients. A first-generation adenoviral vector carrying the *CFTR* cDNA was administered to the nasal epithelium and shown to partially restore cAMP-mediated chloride transport[97]
- Five years after cloning of *CFTR,* Crystal et al. performed the first phase I dose-escalation CF gene therapy study. This was first and foremost a safety study and showed transient inflammatory responses only at the highest dose ($2 \times 10^9$ plaque forming units [PFUs]/patient)[98]
- Six years after cloning of *CFTR,* Caplen et al. provided first evidence that a nonviral gene transfer agent (DC-Chol:DOPE) complexed with *CFTR* cDNA could partially correct cAMP-mediated chloride transport in the nasal epithelium of CF patients[99]
- Ten years after cloning of *CFTR,* the first of six AAV2 trials was published.[100] These trials initially looked encouraging[101] but ultimately were discontinued due to lack of efficacy
- The same year, Alton et al. demonstrated that a nonviral gene transfer agent (GL67A) complexed with a plasmid DNA carrying the *CFTR* cDNA could partially correct cAMP-mediated chloride transport in the lungs of CF patients[53]
- Twenty-six years after cloning of *CFTR,* Alton et al. demonstrated that repeated administration of GL67A complexed with a plasmid DNA carrying the *CFTR* cDNA significantly, albeit modestly, stabilized lung function in CF patients[59]

*CF,* Cystic fibrosis; *CFTR,* cystic fibrosis transmembrane conductance regulator.

The older literature related to CF gene therapy has been reviewed in many publications (e.g., see Griesenbach et al.),[46] and therefore we will provide a brief description and discussion of the key lessons learned and focus on more recent progress in the field.

## Viral Versus Nonviral Gene Transfer Agents

Vectors that carry nucleic acids into cells fall broadly into two categories; viral and nonviral vectors. In general, viral vectors are more efficient because they have evolved to infect cells and therefore carry suitable proteins to overcome at least some of the barriers described later. Adenoviruses and adeno-associated viruses (AAVs) have a natural tropism for the lungs and seemed obvious choices for early CF gene therapy trials.[46] However, preexisting and induced immune responses to the viral vector limit their usefulness for the treatment of a lifelong disease such as CF. To date, we have not seen convincing evidence in either preclinical models or clinical trials to demonstrate that repeated administration of adenoviral or AAV vectors to immune-competent lungs without loss of efficacy is feasible.

In contrast to viral vectors, the simpler structure of nonviral formulations that generally do not contain proteins make them less likely to induce immune responses. Between 1999 and 2004 nine CF gene therapy trials used nonviral GTAs.[46] Combined, these studies presented a scattered picture with some trials detecting vector-specific mRNA and some partial correction of the chloride transport defect, whereas others did not. Proof of concept for efficacy (based on detection of mRNA and partial correction of chloride transport on nPD) of repeated administration (three doses delivered to the nasal epithelium) of a nonviral vector was only assessed in one study.[47]

## Lung Is a Challenging Target Organ

Potent intracellular and extracellular barriers that have evolved to protect the human host from viruses, bacteria, and other inhaled particles also “protect” against inhalation and uptake of inhaled GTAs. Among the intracellular barriers, the nuclear membrane presents a significant hurdle, particularly for nonviral GTAs. Furthermore, there are extracellular barriers, including airway mucus, mucociliary clearance, and mucopurulent CF sputum,[48–50] as well as humoral and cellular immune responses (see Xia et al.[51] for more detailed discussion).

## Recent Progress in the Field

The UK CF Gene Therapy Consortium (GTC; http://www.cfgenetherapy.org.uk/; https://www.youtube.com/watch?v=JiO23xq8LJA) was founded in 2001, consisting of the three groups in Edinburgh, London, and Oxford that had previously conducted CF gene therapy trials. The explicit aim was to share expertise and knowledge in a translational program to assess whether gene therapy could lead to clinical benefit. It is generally considered inappropriate for authors to devote a considerable proportion of a review to their own work. However, the GTC is currently the only group conducting CF gene therapy trials and recently completed a pivotal phase IIb multidose trial. In brief, the GTC has:

a. Following an extensive screening program, determined that the cationic lipid formulation GL67A, first used in the 1990s, remained the most potent nonviral GTA for airway gene transfer some two decades later.[52]
b. Identified that first-generation plasmids used in previous trials contained many immune-stimulatory CpG dinucleotides that may have contributed to the mild “flu-like” symptoms noted in previous single dose lung trials.[53,54] We improved the plasmid (termed pGM169) by removing the CpG islands, codon-optimized the CFTR cDNA, and generated the novel regulatory element, hCEFI, consisting of the elongation factor 1$\alpha$ promoter coupled to the human cytomegalovirus (CMV) enhancer.[55]
c. Undertaken regulatory-compliant multidose toxicology studies in mice[55,56] and sheep,[56,57] supporting progression into a multidose clinical

trial. Interestingly, repeated aerosolization of pGM169/GL67A to mice led to cumulative dose-related expression on repeat dosing, reaching 94 ± 19% of endogenous murine CFTR levels after 12 deliveries. These data further supported progression into a multidose clinical trial.

d. Shown in a single dose, dose-escalation (5, 10, and 20 mL of pGM169/GL67A) phase I/IIa safety trial, that despite CpG-depletion of the plasmid, patients receiving the 10- and 20-mL dose still developed mild “flu-like” symptoms including a fever.[58] The likely explanation is that both the volume administered to the lung and the lipid contribute to the inflammatory response (in addition to CpG sequences). The 5 mL dose (containing approximately 13 mg plasmid DNA) was chosen for the multidose trial.

e. Undertaken a double-blind, placebo-controlled multidose trial. Patients (12 years or older with moderate or mild lung disease) received 5 mL of nebulized pGM169/GL67A or 5 mL 0.9% saline every month for 12 months. The primary end point was a change in lung function measured as a relative change of % predicted $FEV_1$. Efficacy data from 116 patients (who received nine or more doses) were analyzed.[59] The treatment was well tolerated, and the trial met its primary end point, showing a significant, albeit modest, treatment effect in the pGM169/GL67A group versus placebo at 12 months' follow-up (3.7%, 95% confidence interval [CI] 0.1–7.3; *P* = .046; Fig. 53.3A). Prespecified subgroup analysis showed that patients with more severe lung disease at the start of treatment responded better than those with milder lung disease at the start of treatment (see Fig. 53.3B and C). Reasons for this are currently unknown, and various hypotheses should be tested. One simple explanation may relate to the amount of material deposited in the proximal airways, which is likely higher in patients with more severe lung diseases due to sputum-restricted deposition distally into the smaller airways.

**FIG. 53.3** Change in the primary outcome ($FEV_1$% predicted) over a 12-month period of a phase 2b RCT (59) of nonviral CFTR gene therapy *(blue)* or placebo *(red);* (A) within the whole group there was stabilization of the actively treated arm which was significantly ($P < .05$) different than placebo, (B) subjects with baseline $FEV_1 < 70\%$ who demonstrated a pronounced effect, and (C) subjects with baseline $FEV_1 > 70\%$ in whom little effect was seen. *CFTR,* Cystic fibrosis transmembrane conductance regulator; *$FEV_1$,* forced expiratory volume in 1 second; *RCT,* randomized controlled trial. (Modified from Alton EW, Armstrong DK, Ashby D, et al. Repeated nebulisation of non-viral CFTR gene therapy in patients with cystic fibrosis: a randomised, double-blind, placebo-controlled, phase 2b trial. *Lancet Respir Med*. 2015;3(9):684-691.)

The statistically significant albeit modest effect on lung function shown in this trial was paralleled by only minimal changes in the ion transport assays and no detectable vector-specific mRNA. This discordance may relate to the timing and/or sensitivity of the assays, the site of measurement, and/or the relatively small area of airways assessed when using molecular assays and further questions the use of these assays as "go/no-go" decision points in the development of CF gene therapy. The results have raised questions about dose, dose interval, and suitability of placebo, which will be taken into consideration for future studies.

## More Recent Vector Development and Upcoming Clinical Trials

Lentiviral vectors, which integrate into the genome, can transduce dividing and nondividing cells and might therefore be suitable for targeting differentiated cells in the lung. Several groups have investigated lentiviral vectors for airway gene transfer. Although integrating vectors have an inherent risk of inducing insertional mutagenesis, it is important to discriminate between the early gamma retroviral vectors that have been shown to cause leukemia in some patients when used for bone marrow transduction[60] and the more advanced lentiviral vectors, which have not shown evidence of insertional mutagenesis in clinical trials.[61–63]

Lentiviral vectors have no natural lung tropism and therefore require pseudotyping with appropriate envelope proteins to facilitate lung gene transfer. The vesicular stomatitis virus G (VSV-G) protein is commonly used and works well for bone marrow transduction *ex vivo*. However, for transduction of airway epithelium, it is necessary to precondition the tissue with detergents that damage the epithelium and allow access to the basolateral membrane via intercellular spaces.[64] This approach raises safety concerns for translation into clinical trials, particularly in CF patients with chronic lung infections. As a result, several groups, including our own, have investigated the use of other envelope proteins, including the baculovirus protein GP64,[65] proteins from Ebola or Marburg filoviruses,[66] the HA protein from influenza virus,[67] and the F and HN protein from Sendai virus (Fig. 53.4),[68–70] which are viruses that either have a broad tissue tropism (baculovirus) or a natural tropism for the lung (influenza and Sendai virus). We and others have shown that a single dose of lentivirus leads to lifelong stable gene expression in the murine lung (~2 years; Fig. 53.5) and that repeated administration of the vector (10 daily doses or 3 times one monthly doses) is feasible.[65,69,70] To date, there has been no report of insertional mutagenesis or other untoward toxicity in lungs of mice. A direct comparison between the lead nonviral vector GL67A that was used in the recently completed phase IIb CF gene therapy trial (see earlier) and the F/HN-pseudotyped lentiviral vector indicates that the virus is several log orders more efficient in transducing airway epithelial cells, which are the target cells for CF gene therapy.

**FIG. 53.5** Bioluminescent imaging demonstrates luciferase expression out to 22 months in the nose and lungs of mice dosed with the pseudotyped lentivirus vector. (Reused with permission from Griesenbach U, Inoue M, Meng C, et al. Assessment of F/HN-pseudotyped lentivirus as a clinically relevant vector for lung gene therapy. *Am J Respir Crit Care Med*. 2012;186(9):846-856.)

In addition to the envelope proteins, optimization of promoter/enhancer elements that drive recombinant protein expression require careful optimisation.[71] The efficiency, duration of expression, lack of toxicity, and, uniquely, efficacy on repeated administration support progression of the F/HN-pseudotyped lentivirus into a first-in-human phase I/IIa CF clinical trial.

## Outstanding Questions

Many of these questions, although raised in the context of gene therapy, also relate to the small molecule modulator field; certainly, lessons learned from one approach may have implications for others.

### How Much Cystic Fibrosis Transmembrane Conductance Regulator Expression Do We Need?

Patients with certain “mild” CF mutations who retain approximately 10% of residual CFTR expression per cell do not suffer from lung disease, although other organs may be affected.[72] Phenotypic manifestations of CFTR dysfunction reflect the degree of transepithelial CFTR function *in vivo*, which may also provide useful information in guiding the “how much is enough?” question.[73] *In vitro* cell mixing experiments have shown that approximately 10% of non-CF cells restore CFTR-mediated chloride secretion when mixed with 90% of CF cells in a monolayer.[74] In a separate study, it was shown that CFTR must be expressed in at least 25% of cells grown in a monolayer to restore mucus transport.[75] However, these studies do not address whether complete correction of CFTR expression in 10% cells is equivalent to a low level (approximately 10%) of CFTR expression in all cells. We currently also do not know whether the various forms of genetic medicines are more likely to achieve the former or the latter.

### Which Cells Do We Need to Target for Restoration of Cystic Fibrosis Transmembrane Conductance Regulator Function?

CFTR is expressed in various cell types in the lung, including submucosal glands, ciliated epithelial cells, and goblet cells. It is currently unknown which cells express the CFTR transgene following gene transfer. To correct submucosal glands, any agents applied topically to the airways, such as gene transfer vectors and oligonucleotides, will need to negotiate ducts filled with mucus; this barrier may be substantial. It has been postulated that CFTR is also expressed in macrophages and neutrophils. Whether this leads to an intrinsic defect in host defense in the CF lung is still widely debated[76] and needs to be resolved before deciding whether these cell types are suitable targets.

## Should Studies in Cystic Fibrosis Models Form a "Go/No-Go" Decision Point Before Progression Into Clinical Trials?

CF mice do not acquire spontaneous airway infections or develop CF lung disease, but the nasal epithelium shows the characteristic CF chloride and sodium transport defects.[77] However, the relevance of measurement of CFTR function in the murine nose (via *in vivo* potential difference) has been called into question by Ostrowski et al. who showed that expression of human CFTR under the transcriptional control of a cilia-specific promoter did not correct ion transport in CF knockout mice.[78] In addition, Grubb et al. have suggested that the olfactory, rather than the respiratory, nasal epithelium mainly contributes to the ion transport defect in CF mice.[79] Thus the CF mouse has been of limited value as a steppingstone to human gene therapy trials[80] and, in our opinion, should not be used as a go/no-go decision point for progression into gene therapy clinical trials. Whether correction of lung disease in CF knockout pigs or ferret is a better model to predict clinical success remains to be seen. Currently, these animals die shortly after birth due to intestinal disease and therefore are not yet available in large enough numbers to conduct clinically meaningful studies. In addition, it is currently unclear whether the CF-like pathology is a suitable enough mimic of human disease to be used as a critical decision point for therapeutic development.

## Are There Other Genetic Medicine-Based Approaches?

In addition to the *"classical"* gene therapy described previously, mRNA as a template for CFTR gene supplementation has long been appealing as an alternative to DNA-based gene delivery because it avoids the rate-limiting step of nuclear entry into nondividing airway epithelial cells, being translated rapidly and efficiently directly in the cytoplasm[81] and chemical modifications made to enhance efficacy of mRNA therapy have been successful.[82] Proof of concept for the efficacy of repeated pulmonary delivery of chemically modified mRNA has been established in a murine model of surfactant protein B deficiency,[83] but due to a comparatively long transcript the development of CFTR mRNA therapy is more complex and has not been reported yet.

In addition to gene and mRNA therapy, *correction* of the genetic defect in the genome (gene editing) or in the mRNA (mRNA repair) are being developed. Genome editing using zinc finger nucleases, TALENS, or the CRISPR/Cas9 system are revolutionizing research and therapeutic strategies for many diseases.[84] In the context of CF, genome editing has been used to repair CFTR mutations and restore protein function in cell lines,[85] intestinal organoids,[86] and CF patient–derived induced pluripotent stem cells (iPS) *in vitro*.[87,88] This technology will be very useful for developing mutation-specific cell lines for drug screening.

Wong et al. have developed protocols to allow differentiation of human pluripotent stem cells into mature airway epithelium expressing functional CFTR protein,[89] which may lead to speculation that genome-edited iPS cells could be differentiated into airway epithelial cells or airway progenitor cells, which could then be used to replenish cells in the CF lung. However, there are currently no successful reports of cell therapy in the lung due to the structural complexity of the organ.

The technology may also lead to proposals for genome editing of airway epithelial cells *in vivo*. However, there are several flaws with this. First, genome editing *in vivo* will require the delivery of the genome-editing molecules, as well as appropriate wild-type CFTR sequences, required for homologous recombination-based repair of the mutant CFTR, which is yet more complex than standard gene therapy. Second, current thinking is that airway epithelial cells are terminally differentiated and do not undergo homologous recombination. Third, one might argue that *in vivo* genome editing of airway progenitor cells is an alternative. However, these cells are buried beneath the surface epithelium and difficult to access with gene therapy vectors. In addition, airway progenitor cells divide very slowly, again making homologous recombination inefficient. The development of alternative gene editing strategies may, in the future, be able to overcome these current problems.

Different strategies have been suggested to *"repair"* mutations in the CFTR mRNA. Small molecule drugs such as ataluren, which bypass premature stop mutation, are being assessed in clinical trials (described in detail previously). Alternative strategies are based on direct repair of the mRNA using a short RNA oligonucleotides. QR-010, developed by ProQR Therapeutics, targets the Phe508del mutation and is currently being assessed in early phase clinical trials (NCT02532764, NCT02564354).

## Evaluating Therapies Targeting the Basic Defect in Clinical Trials

There has never been a more crucial time to be able to identify suitable end points for clinical trials in CF. Clinical trials of CFTR modulators have already provided us with a wealth of information about trial design and end points, which will guide those in the future. The potential to modify a disease course (as reported for ivacaftor reducing the decline in lung function over time in older subjects) means that questions such as when to start therapy or the severity of disease for which they are recommended are important, particularly in areas of the world where prohibitive cost of drugs may impact on access to patients. It is likely that those with the greatest to gain from such treatments will be those with mild disease (i.e., before the onset of irreversible structural change and established infection). Although $FEV_1$ is well established by the regulatory authorities as an acceptable outcome on which to evaluate efficacy in clinical trials, other measures remain in relative infancy. The role of pulmonary outcome measures such as LCI, as a more sensitive marker than $FEV_1$, is a continued area of development, and standardized protocols now exist to promote quality control (e.g., via the US Cystic Fibrosis Foundation

Therapeutic Development Network or European CF Clinical Trials Network). Proof that LCI could be used to demonstrate efficacy in the ivacaftor trial involving patients with normal spirometry was important to the field—LCI is now also the primary outcome in the lumacaftor/ivacaftor combination therapy trial in those with mild disease. Pulmonary efficacy outcome measures for very young children may be more challenging to capture in multicenter studies; however, it is also of note that the regulatory agencies have accepted extrapolated efficacy data from older patients for ivacaftor, in the presence of data on safety outcomes and markers of CFTR function (e.g., sweat chloride) in this age group.[20] There may be a role for radiologic outcomes (e.g., high-resolution computed tomography [HRCT]) in late-phase clinical trials in young children to detect efficacy; however, there are concerns over additional radiation exposure[90] in patients for whom a degree of radiation exposure is already a standard component of their CF care. However, HRCT is being considered as an outcome measure for trials in young children. Imaging modalities without radiation exposure may offer an alternative in the future, including magnetic resonance imaging (MRI)[91] with or without hyperpolarized gas (helium or xenon).[92]

Sweat chloride concentrations and/or nPD measurements have often been included in the trial protocols for clinical trials of CFTR modulators and for the latter, gene therapies. These outcomes are of interest because they provide organ-specific information about CFTR function. Sweat chloride concentration has been shown to dramatically reduce following initiation of CFTR small molecule therapies, although changes within patients do not correlate well with lung function outcomes.[93] Within the airway, nPD measurements of epithelial CFTR chloride transport have also attempted to quantify CFTR activity. Changes in nPD following ivacaftor treatment were relatively small in comparison with the magnitude of lung function and nutritional improvement seen, raising questions about the degree of “normalization” of nPD required to demonstrate CFTR functional efficacy; the measurement is also variable and perhaps lacks sensitivity. Organoids, hollow structures formed *ex vivo* from epithelia obtained from, for example, rectal suction biopsies, are an evolving area of interest because these models allow assessment of CFTR function at the individual patient level (an approach that may be particularly relevant for patients with very rare or uncategorized CFTR mutations).[94] This would enable a personalized approach to predicting likely efficacy of a CFTR modulator.

## Challenges for the Field

Aside from the technical challenges associated with discovering novel agents and testing them as sole or combination agents *in vitro* or *in vivo*, there are other significant challenges to consider. These include managing patient expectations and designing future clinical trials in the limited number of CF patients worldwide, particularly with powering late-phase clinical trials appropriately when effect sizes may be expected to be small. In comparison with the early trials of CFTR modulators when comparison was made with placebo, as these drugs become standard care for an increasing proportion of the CF population, this will no longer be appropriate. Adding new molecules onto these “standards of care,” particularly if combined effects are sought, will require careful consideration of trial design and effect size. The field is still in its infancy, and as CFTR modulators become established as part of routine care in CF, the long-term impact on outcomes will become clear. National and international CF registries will be able to play an important role in capturing this impact at the population level in the real-world setting. In an era where treatment options are becoming personalized according to genotype, ensuring that such information is known for each patient is important for treatment options and eligibility for clinical trials.

The CFTR modulators licensed for use are associated with high per-patient drug costs—which is particularly relevant for treatments that are likely to be taken on a lifelong basis. The impact of this cost from a patient perspective will vary across the globe and according to whether there is an insurance-based or national health care system.

## Summary

It is difficult to underestimate the impact of CFTR modulators over recent years and the momentum driving investigation into further-refined treatments targeting the underlying molecular defect in CF. The impressive results of the clinical trials in patients with class III mutations may be difficult to follow, and it will be important not to set the therapeutic bar too high based on these data, but increased understanding of the abnormalities in the structure and function of CFTR protein will help to better understand the approach or approaches required for normalizing function and in doing so help to rationalize the design of clinical trials. In addition, to identify progressively more efficacious drugs, determining the appropriate patient population for each approach will be key. Long-term follow-up to understand not only potential impact on disease modification but also the safety profile of these novel agents is paramount. In the context of such success with certain of these small molecule approaches, questions are sometimes raised about the relevance of gene therapy and other genetic approaches, which are, undeniably, some way behind. We perceive three major benefits of this approach: (1) gene replacement is completely mutation agnostic, so applicable to all classes of mutations including those that are incompletely understood; (2) the potential for long duration expression translating into infrequent treatment, and (3) topical application reducing the potential for drug-drug interactions. The latter are substantial for current, systemically absorbed CFTR modulators. Furthermore, we consider that there could be substantial synergy by combining gene-based and small molecule approaches, to build on the potential of each.

Overall, we are enthusiastic about the potential for therapies targeting the basic defect. Maybe future optimal approaches will harness the benefits of more than one of these approaches and lead to considerable synergy.

## Declaration of Interests

GD, UG, and EA have no interests to declare. JCD has served on advisory boards, undertaken educational activities, and lead clinical trials for which Imperial College London has received fees, for the following companies relevant to this chapter: Vertex, PTC, AlgiPharma, Novartis, Galapagos, Bayer, Chiesi. JCD, GD, UG, and EA are part of the UK CF GTC, which has received funding from the UK Cystic Fibrosis Trust and the National Institute for Health Research (NIHR).

## Acknowledgments

Work conducted by EA, JCD, and UG is supported by the NIHR Respiratory Disease Biomedical Research Unit at the Royal Brompton and Harefield NHS Foundation Trust and Imperial College London. GD is supported by a NIHR Academic Clinical Lectureship at University College London and by the NIHR Biomedical Research Centre at Great Ormond Street Hospital for Children NHS Foundation Trust.

# New Concepts in Children's Interstitial and Diffuse Lung Disease

*Robin Deterding MD*

The field of children's interstitial and diffuse lung disease (chILD) has undergone tremendous development over the past decade, driven by new genetic discoveries, improved techniques in imaging and lung biopsy, and organized efforts to better define clinical phenotypes (Table 54.1).[1] This progress has resulted in recognition of new disorders, the definition of a diffuse lung disease pediatric classification system, and formation of the chILD Foundation [http://child-foundation.org/(USchILD); http://www.childlungfoundation.org/(UKchILD)] and chILD research networks around the world. Research networks in the USA and the European Union now have prospective multicenter registries. Chapters in this section have been organized to align with these new developments and to provide the reader with a new framework to care for these children.

**Table 54.1**

## Diffuse Pediatric Lung Disease Classification

| Classification Category | Specific Disorders | Common Age Presentation |
|---|---|---|
| **Disorders More Common in Infancy** | | |
| Developmental Disorders | Alveolar capillary dysplasia with misalignment of pulmonary veins | Birth |
| Growth Abnormality Disorders (alveolar simplification) | Pulmonary hypoplasia, chronic neonatal lung disease associated with chromosomal disorders, associated with congenital heart disease | Birth |
| Specific Conditions of Unknown Etiology | Neuroendocrine cell hyperplasia of infancy (NEHI), pulmonary interstitial glycogenosis (PIG) | Birth—1 month (PIG)<br>Infancy—24 months (NEHI) |
| Surfactant Dysfunction Mutations | Surfactant protein B *(SFTPB)*, surfactant protein C *(SFTPC)*, ATP-binding cassette A3 *(ABCA3)*; *NKX2.1* (thyroid transcription factor 1); and histology consistent with a surfactant mutation | Birth *(SFTPB)*<br>Birth—Adulthood *(SFTPC, ABCA3 NKX2.1)* |
| **Disorders Related to Systemic Disease** | Immune-mediated collagen vascular disease, storage disease, sarcoidosis, and Langerhans cell histiocytosis. | Childhood—Adolescence |
| **Disorders of the Normal Host/Environment Exposure** | Infectious or postinfectious process, hypersensitivity pneumonitis, aspiration, eosinophilic pneumonia. | Infancy—Adolescence |
| **Disorders of the Immunocompromised Host** | Opportunistic infections, transplantation and rejection, therapeutic interventions | Infancy—Adolescence |
| **Disorders Masquerading as Interstitial Lung Disease** | Pulmonary hypertension, cardiac dysfunction, veno-occlusive disease, lymphatic disorders | Birth—Adolescence |
| **Unknown** | Pulmonary biopsy tissue that cannot be classified | |

The cliché that "children are not little adults" is a good paradigm to explain the confusing early literature on children with ILD.[1,2] Although adult patients with desquamative interstitial pneumonitis (DIP) were found to have a good prognosis, children with DIP had high mortality.[3,4] DIP in children is now a recognized pathologic phenotype, which is consistent with congenital surfactant mutations that have significant mortality.[5,6] Conversely, children with severe ILD were frequently labeled as cases of idiopathic pulmonary fibrosis (IPF),[7,8] which is synonymous histologically with usual interstitial pneumonia (UIP), a leading cause of mortality in adult ILD.[9] However, on further review, the histologic diagnostic criteria for UIP characterized by fibroblast foci have not been seen in infants and young children, and have been seen in only one older adolescent.[10] New disorders in young children less than 2 years of age—not previously described in adult patients—were also reported. There were disorders, such as neuroendocrine cell hyperplasia of infancy (NEHI),[11,12] pulmonary interstitial glycogenosis (PIG),[13] and alveolar capillary dysplasia with misalignment of pulmonary veins (ACDMPV).[14] The differences in diagnosis highlighted the fact that forcing children with ILD into adult classification systems did not serve their interests and signaled the need to reorganize thinking in this area, and to create a pediatric-specific diffuse lung disease classification system.[6,9]

## New Concepts, Terminology, and Classification

The field of diffuse lung disease is large and includes commonly recognized pediatric diseases. For example, diffuse lung diseases, such as cystic fibrosis, chronic lung disease of prematurity, and pulmonary infections have recognized clinical presentations and diagnostic testing. However, once these more recognized disorders have been ruled out, some children remain undiagnosed and are labeled with the general term ILD, as if this were a final diagnosis, or they are listed as having unknown lung disease. The concept of chILD syndrome was created to further define this subset of poorly diagnosed children with diffuse lung disease.[15] chILD syndrome is defined as a child who has three to four of the following findings without a known underlying lung disease to fully explain the clinical condition: (1) respiratory symptoms, such as coughing, rapid breathing, or exercise intolerance; (2) physical signs, such as crackles, adventitial breathing sounds, digital clubbing, or intercostal retractions; (3) a low blood oxygen tension or hypoxemia; and (4) diffuse parenchymal abnormalities on chest imaging.[16] chILD syndrome is a constellation of findings that should signal the clinician that further diagnostic evaluation is indicated to reach a definitive diagnosis. Using this definition, Van Hook reviewed two large data sets of young children with biopsy-proven diffuse lung disease and found this definition to be sensitive to make the diagnosis of chILD syndrome.[17] Furthermore, if a child with a known diagnosis has symptoms out of proportion to the recognized disease, they may still have chILD syndrome and require further evaluation for a secondary diagnosis. This is an important nuance, as some chILD diseases occur in conjunction with other known conditions, such as congenital heart disease and chronic lung disease of prematurity or PIG.[6] (See Chapter 56 for further discussion.)

The designation of a pediatric-specific classification system for diffuse lung disease was essential. Based on the expertise of Dr. Claire Langston and her extensive experience reviewing lung biopsies in children with diffuse lung disease, a new clinical and pathologic classification system was proposed, which incorporated features unique to children, especially the category "disorders more common in infancy" (see Table 54.1).[5] A landmark study, published in 2007, reported on the application of this classification system by a multidisciplinary cooperative that reviewed more than 180 lung biopsies over a 5-year period in children less than 2 years of age at 11 children's hospitals in North America.[6] This review further established that the Langston classification system could realistically be applied, and was appropriate, for infants and young children. Chapters in the chILD section are organized loosely around these categories, and should provide a diagnostic framework for children with diffuse lung disease. The Europeans have used a similar classification with minor differences.[18] Refinements of this classification system are evolving and will continue to evolve as more genetic disease associations are identified with the increased use of exome and genome sequencing for the diagnoses of unknown disease.

Retrospective studies in North America and Europe illustrate that children with chILD syndrome are overly represented in infants and younger children.[5,6] The application of the Langston classification system and an adapted version in Europe also demonstrated that over half the patients reviewed could be classified in the category "disorders more prevalent in infancy."[6,18] It is less clear if the Langston pediatric classification system is appropriate for older children. A recently published review of more than 180 lung biopsies in children older than 2 years of age at multiple centers in North America, using the same methodologies as the previous under 2 years of age retrospective review, suggests that the classification system does work well for these older children.[19] Biopsies in older children were rarely classified in the category "disorders more common in infancy"; older children had significantly more biopsies classified in the categories "disorders related to system disease" (see Chapters 57 and 58) and "disorders related to the immunocompromised host" (see Chapter 64).[19] This is further illustrated in the chapters that deal with these categories.

## General Diagnostic Approach

The evaluation of chILD can be complicated, expensive, and associated with a risk for significant morbidity. To address these concerns, clinical guidelines focused on infants and young children have been published.[20]

Any newborn or child presenting with diffuse lung disease should have a complete history and physical (H&P) performed.[20,21] Although most diagnoses are not established with an H&P, specific clues can be uncovered that may be suggestive. Important history questions should include: birth history, a complete family history for use of oxygen or pulmonary deaths in any age family member to suggest genetic disease, previous pulmonary infections to suggest lung injury, family history of autoimmune disease, and a thorough environmental history to evaluate for hypersensitivity pneumonitis.[20,22] A complete physical examination should evaluate for nutritional indices, sinopulmonary disease, chest wall deformities, skin rash, clubbing, and neurologic disorders.

Other noninvasive testing should then be completed to rule out known causes of lung disease, such as cystic fibrosis, primary ciliary dyskinesia, aspiration, immunodeficiency, hypersensitivity pneumonitis, pulmonary infections, or autoimmune disease. An echocardiogram should be obtained to rule out masqueraders of lung diseases, such as congenital heart disease and pulmonary vein abnormalities, and to identify the presence of pulmonary hypertension, which may require more aggressive treatment, and may be associated with a worse prognosis.[23,24]

Imaging is often ordered to determine the pattern of diffuse lung disease. Chest radiographs are nonspecific and not helpful for specific diagnoses. Volume-controlled inspiratory and expiratory high-resolution computerized topography (HRCT) has been the most helpful way to obtain quality images for children with chILD syndrome, and may suggest bronchiolitis obliterans, pulmonary alveolar proteinosis, hypersensitive pneumonitis, or neuroendocrine cell hyperplasia.[25,26] The lowest amount of radiation possible should always be used. In children less than 4 years of age, or in those neurologically impaired, HRCTs will likely require sedation for optimal scans unless newer fast scanners are used, and some children may require prone positioning if atelectasis is seen posteriorly.[20,27] Though HRCT scanning is available at most hospitals around the country, it is highly recommended that scans in newborns, infants, and young children be completed at centers with expertise and protocols developed to optimize HRCTs for children with chILD using the lowest radiation dose possible. Newer imaging modalities are also emerging, such as hyperpolarized 3He ventilation magnetic resonance imaging (MRI), which may be more sensitive for early lung disease and is done without radiation.[28]

Infant pulmonary function testing is currently used to evaluate children with cystic fibrosis and chronic lung disease of prematurity. Limited, but important, data exist for children with chILD syndrome. Infant pulmonary functions can be completed reliably in children with NEHI at centers experienced in these techniques, and may be helpful because a classic pattern of airway obstruction and gas trapping has been reported in infants and young children.[29] Data suggest that the severity of small airway obstruction may correlate to the prominence of bombesin staining (a marker for neuroendocrine cells) in the lung tissue,[30] and that measures of small airway obstruction also may trend toward correlation with lower weight.[29] Some experienced chILD centers currently use infant pulmonary function data in conjunction with other testing (HRCT imaging, bronchoscopy, and clinical findings) to determine the need for a diagnostic lung biopsy in a child with classic findings for NEHI. The American Thoracic Society (ATS) consensus guidelines address the ideal timing and use for infant pulmonary function tests (PFTs).[20] New techniques with a lung clearance index have not yet been tested in children with chILD.

Genetic testing has emerged as a significant consideration in the evaluation of children with chILD, especially for inborn errors of surfactant metabolism. Any child with chILD syndrome without a clear etiology, and especially those who present with a family history of infant deaths, prolonged oxygen use, or family members with IPF, should have testing for abnormalities in surfactant metabolism.[31] Clinical testing is available through clinical laboratory improvement amendments (CLIA)–certified laboratories. A useful site for genetic information and laboratory testing is GeneTests (https://www.genetests.org/). The type of genetic testing is related to clinical presentation, so that those who present immediately in the newborn period with respiratory failure and pulmonary hypertension may be more likely to have surfactant protein B *(SFTPB)* and ATP-binding cassette A3 *(ABCA3)* mutations, while those who present later may be more likely to have surfactant protein C *(SFTPC)* mutations.[32] Genetic testing for (ABCA3) mutations has become very important for prognosis, as mutations that are null/null are associated with death or transplant at 1 year.[33] For those infants who present with respiratory failure and congenital hypothyroidism, investigations for mutations in the *NKX2.1* or thyroid transcription factor-1 *(TTF-1)* gene should be performed because this is a more recently recognized gene that regulates surfactant proteins.[34] NKX2.1 can also present with the complete triad of "Brain, Thyroid, Lung Syndrome" or a combination of any two organs. Children with chorea should be checked for NKX2.1[35] and evaluated for lung disease. As the time to sequence these genes has decreased and test results can become available in weeks (instead of months), many centers wait for test results before proceeding to lung biopsy if the child's clinical status is stable. If test results are unclear or if testing is negative, a lung biopsy may be indicated. There is still a great deal to learn about both genetic and environmental modifiers for these genes. Chapter 57 provides a more detailed discussion of disease associated with abnormal surfactant metabolism. Recently, the forkhead box transcription factor *(FOXF)* gene has been associated with familial cases of children with ACDMPV, and testing may be indicated for this fatal disorder.[36] Finally, more genetic mutations are likely to be found in children with chILD, such as NEHI, which has been shown to occur in families,[37] and some surfactant genetic abnormalities may be important modifiers of more common diseases such as respiratory distress of the newborn,[38,39] and adult diseases, such as chronic obstructive pulmonary disease (COPD).[40–42] Exome and whole genome technologies are becoming more available in a timely manner and at more reasonable price points. Also, there are pulmonary genetic panels that examine many genes. Genetics will clarify how many unknown chILD conditions exist and allow better mechanistic understanding of the disease. Many new diseases are being defined, and this will only grow with enhanced genetic techniques. Table 54.2 provides a list of recently described serious chILD diseases with genetic causes, such as mutations in filamin A (FLNA),[43] coatomer subunit alpha (COPA),[44] GATA-2 transcription factor,[45] Methionyl-tRNA synthetase (MARS),[46] lipopolysaccharide-responsive and beigelike anchor protein (LRBA)[47] and CTLA4.[48]

## Table 54.2

**New Genetic Mutations Associated With Diffuse Lung Disease**

| Disease | Genetic Defect |
|---|---|
| Lethal cystic lung disease | FLNA (filamin A, alpha) mutations |
| Severe pediatric PAP | MARS (methionyl-tRNA synthetase) mutations |
| Autoimmunity with arthritis, vasculitis, and chILD | COPA (Coatomer subunit alpha) mutations |
| Immunodeficiencies with monocytopenia, infections, lymphatic abnormalities, chILD, and PAP | GATA-2 transcription factor mutations |
| Immune-mediated lung disease—GLILD/CVID-like | LRBA (lipopolysaccharide-responsive and beigelike anchor protein) mutations |
| Immune-mediated lung disease—GLILD/CVID-like | CTLA 4 haploinsufficiency |

*CVID*, Common variable immunodeficiency; *GLILD*, granulomatous-lymphocytic interstitial lung disease; *PAP*, pulmonary alveolar proteinosis.

Bronchoscopy and bronchoalveolar lavage (BAL) remain important diagnostic tools in the evaluation of children with chILD syndrome. This is particularly true in children who have pulmonary hemorrhage, or who are immunocompromised to diagnose infection.[49–51] Bronchoscopy also may be important to rule out anatomic abnormalities and to suggest alveolar proteinosis,[52] pulmonary histiocytosis,[53] sarcoidosis,[54] and Niemann-Pick disease.[55] Active research is currently underway to identify diagnostic BAL biomarkers that may aid diagnosis, provide prognostic information, and shed insight into the pathophysiology of chILD syndrome.[56] More specific information about the use of bronchoscopy and BAL is addressed in the following chapters.

Lung biopsy remains the gold standard for diagnosis when the less invasive testing is negative or inconclusive.[20,57] The pediatric classification system relies heavily on histologic diagnosis, and the application of this classification system to lung biopsies is likely to provide a classification category or the diagnosis of the chILD syndrome.[6] At this time, only lung biopsies can accurately establish a diagnosis of pulmonary hemorrhage with diffuse capillaritis,[50] pulmonary interstitial glycogenosis,[6,13] alveolar simplification,[6] and ACDMPVs.[5] Lung biopsies also will likely provide the final diagnosis for infections in the immunocompromised patient, NEHI, unclear genetic testing for surfactant mutations, hypersensitivity, follicular bronchiolitis, and other lymphocytic disorders in chILD syndrome.[6,58,59] Newer techniques are emerging to evaluate tissue with advanced staining techniques for many protein markers simultaneously, to better define disease mechanisms.

When weighing the decision to pursue a lung biopsy, many factors that relate to the severity of illness, the progression of disease, and the skill of the surgical and pathology team should be considered. Any surgical approach should be the least invasive approach, and most centers now consider this to be a video-assisted thoracoscopy (VATS).[60] Centers experienced in chILD and VATS have shown that a chest tube may not be needed outside the operating room and may be pulled in the operating room if a simple lung biopsy was performed in a child who does not require positive pressure ventilation postoperatively.[61] Removing the chest tube early may also decrease pain, radiation, length of stay, and cost of care.[62] This is particularly important in chILD syndrome where splinting and pain may create scenarios that derecruit lung and prolong the hospital course. Selecting and processing the tissue is critical to making the correct diagnosis, and this must include selecting the best site for the biopsy, inflating the lung tissue for fixation, saving tissue for electron microscopy, and freezing tissue for future evaluation. Choosing a biopsy location is frequently aided by an HRCT, and a recent study in NEHI suggests that more than one biopsy site may be required to make this diagnosis.[30] Guidelines for tissue handling have been published by the chILD research pathology working group and should be followed.[63] Because experience reviewing the lung tissue in these rare conditions is limited, sending the slides for expert review is sometimes indicated.

## Resources for Families and Physicians

The pursuit of improved care and cures for children with rare diffuse lung disease requires partnerships between families, clinicians, and foundations. Private foundations frequently provide advocacy and resources for family education and support, as well as funding, to move these fields forward through research.

# Rare Childhood Lung Disorders

*Daniel Lesser MD, Lisa R. Young MD, James S. Hagood MD*

## Introduction

Although some respiratory diseases occur rarely in the pediatric population, knowledge of these disorders is valuable from a number of perspectives. Timely diagnosis and treatment of rare disorders can be made only if the practitioner is familiar with the entity in question. Furthermore, elucidation of the pathophysiology underlying rare disorders can be applied to understanding both normal respiratory physiology and related but more prevalent disorders. Many rare lung disorders are covered in other chapters. This chapter characterizes both selected disorders with a primary respiratory component and respiratory disease occurring secondary to systemic disorders, with emphasis on interstitial lung disease. The diseases covered may present predominantly during childhood, such as respiratory disorders of the lymphatic system, or primarily during adulthood but with implications for pediatric patients, such as pulmonary alveolar microlithiasis (PAM) and alpha-1 antitrypsin (AAT) deficiency. Foundations provide invaluable information, support, and advocacy to families and patients affected by rare diseases and also function as important resources for practitioners. This chapter therefore directs the reader to selected disease-specific groups.

# Respiratory Disorders of the Lymphatic System

A number of rare disorders related to dysregulation of lymphatic development occur in pediatric patients from infancy to adolescence. The normal pulmonary lymphatic system is composed of two interconnected pathways: one drains the subpleural space and outer surface of the lung, while the other follows bronchovascular bundles to drain the deeper portions of the lung (see Chapters 6 and 36).[1] In humans, the pulmonary lymphatic system begins to form approximately 6 weeks into embryonic growth with sprouting of distinct endothelial cells directly from the developing venous system.[2] A number of growth factors that direct development of the lymphatic vasculature have been identified,[3] and the pathophysiology leading to lymphatic dysfunction varies among the disorders described in this section. For example, disordered embryonic development has been hypothesized to play a role in pulmonary lymphangiectasia (PL), a disorder that often presents in the neonatal period. In disorders that present outside of the neonatal period, such as lymphangiomatosis, disease is associated with abnormalities of lymphatic growth. Furthermore, a significant number of children with pulmonary lymphatic disorders also manifest lymphatic involvement of other organ systems, congenital cardiac disease, and chromosomal disorders. This section describes disorders associated with lymphatic dysfunction affecting the respiratory system. The reader is referred to Chapter 69 regarding congenital chylothorax.

## Pulmonary Lymphangiectasia

### Epidemiology

PL is characterized by dilatation of pulmonary lymphatic vessels and disordered drainage, leading to the accumulation of lymph within the lungs and a spectrum of respiratory disease. Although its exact incidence is not known, it has been estimated that 0.5%–1% of neonates who die in the neonatal period have PL.[1] The majority of reported cases occur sporadically, and most present in the neonatal period or during infancy. However, cases of PL have also been described to occur during childhood and into adulthood.[4]

## Etiology and Pathogenesis

One commonly used classification system for PL distinguishes between disease caused by a primary developmental defect and that occurring secondary to an obstructive process impeding normal lymph drainage.[3] It has been hypothesized that primary PL occurs secondary to failure of normal regression of the large lymphatic vessels, observed in the embryo at 9–16 weeks of gestation.[3] A recently described murine model of PL was generated by expressing vascular endothelial growth factor (VEGF)-C on a lung-specific promoter.[5] Lymphatic growth is regulated in part by the lymphangiogenic receptor VEGFR3, and mice lacking this gene die shortly after birth from failure of lung inflation.[6] Some infants with primary PL present with disease that seems confined to the respiratory system, while others display more generalized symptoms characterized by lymphedema and extrathoracic involvement.[3] Recent studies in families with inherited isolated forms of lymphedema have identified eight genes causing lymphedema (i.e., *FLT4* [encoding VEGFR3] [MIM 153100], *FOXC2* [MIM 153400], *SOX18* [MIM 607823], *HGF* [MIM 142409], *MET* [MIM 164860], *CCBE1* [MIM 235510], *PTPN14* [MIM 603155], and *GJC2* [MIM 608803]).[7] Secondary causes of PL usually involve congenital cardiac diseases associated with obstructed pulmonary venous flow. Thus hypoplastic left heart syndrome, congenital mitral stenosis, and pulmonary vein atresia have all been associated with PL.[3,8] In addition to cardiac disease, thoracic duct agenesis and infection may also block lymphatic drainage and cause PL.

## Clinical Features

A number of chromosomal disorders are associated with PL, including Noonan syndrome, Hennekam syndrome, yellow nail syndrome, and Down syndrome.[1,3] Children with PL associated with chromosomal disorders are more likely to present with generalized lymphangiectasia. These patients may display a less severe pulmonary component and may have a better prognosis when compared with those who present with primarily pulmonary disease during the neonatal period.[1]

At birth, infants with PL often present with respiratory distress that progresses rapidly to respiratory failure.[1] Chylous pleural effusions may be prominent, but a significant number of children with PL do not present with effusions.[1] Individuals who first develop symptoms later in infancy or during childhood usually display less severe disease when compared with those with neonatal onset. In later-presenting forms, initial symptoms include chronic tachypnea, recurrent cough, and wheezing.[4] PL in these individuals has been associated with chylothorax, chylopericardium, and chylous ascites.[3] These patients have frequent respiratory exacerbations, possibly related to lower respiratory tract infection that leads to transient worsening of lymphatic drainage.[1,4]

## Imaging

The diagnostic workup of the child with suspected PL includes plain chest radiography, high-resolution tomography of the chest (HRCT), and lung biopsy. Chest radiography often reveals interstitial infiltrates and hyperinflation, with or without pleural effusion.[1] HRCT shows thickening of peribronchovascular septa and septa surrounding lobules (Fig. 55.1).[3] Lung biopsy, the "gold standard" for diagnosing PL, is characterized by the appearance of dilated lymphatic vessels located in the interlobular septa, near bronchovascular bundles and/or within the pleura.[8] Dilated lymphatic vessels may occasionally appear cystic.[2] In addition to lymphatic findings, lung biopsy may also show thickening and widening of interlobular septa.[2] The risk of worsened lymphatic leak should be considered in the decision to proceed with lung biopsy. Because lymphangiectasia may be part of a systemic dysplasia, consideration should also be given to careful evaluation for extrapulmonary disease manifestations, such as gastrointestinal involvement, bone disease, or skin lesions from draining lymphatics.

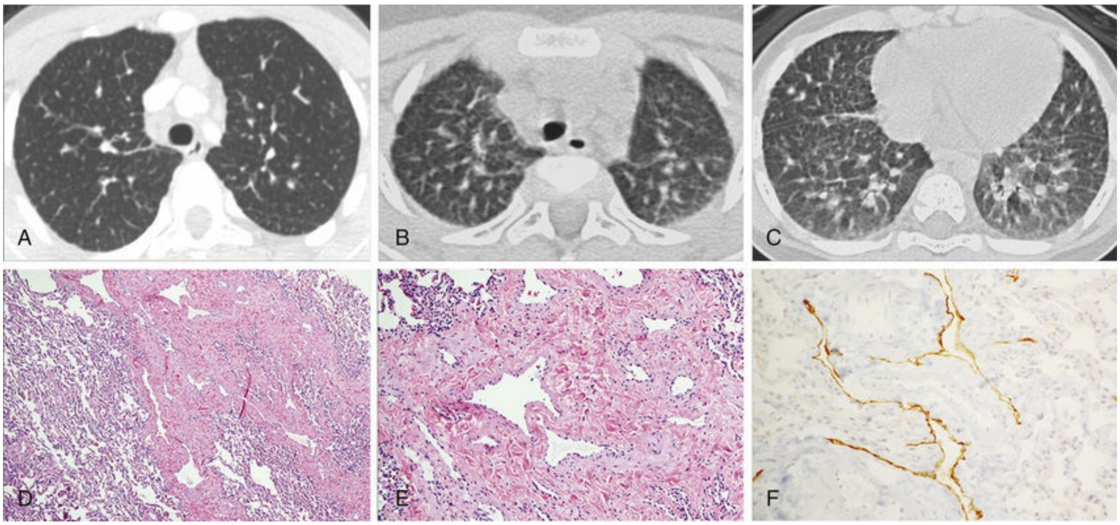

**FIG. 55.1** Chest high-resolution computed tomography from an 8-year-old (A) and a 2-year-old (B and C) with lymphangiectasia. Imaging shows variable intensity of interlobular septal thickening. Both children presented with nonspecific respiratory symptoms and recurrent pneumonia without identification of pathogens; neither had overt extrapulmonary manifestations of lymphatic dysplasia. Lung biopsy shows septal widening with prominent and muscularized lymphatics (D and E, hematoxylin and eosin), as illustrated by D240 immunostaining highlighting the lymphatic endothelium (F). (Cases provided by Lisa R. Young, MD, Cincinnati Children's Hospital Medical Center, Susie Millard, MD, Helen DeVos Children's Hospital and Michigan State University, and Gail Deutsch, MD, Seattle Children's Hospital.)

## Management

There is no known cure for PL, and treatment is primarily supportive. Respiratory failure in a significant number of neonates with PL is refractory to conventional positive-pressure ventilation and high-frequency oscillation. In these cases, inhaled nitric oxide and extracorporeal membranous oxygenation (ECMO) have been used with variable success.[8] Therapy for older children with PL includes supplemental oxygen, judicious use of antibiotics for bacterial respiratory infection and treatment for recurrent wheezing or cough.[4] A number of medications have been reported to be effective for the management of PL and chylothorax in case reports and small series, but none have been tested in randomized clinical trials.

## Prognosis

Although the natural course of PL is variable among individuals, the disease has historically carried a high mortality rate when diagnosed in the neonatal period. One report suggests improved survival with aggressive interventions and modern neonatal intensive care.[4] Subsequently, however, Mettauer et al. have reported survival in only one of seven children referred to their tertiary center.[8] The authors concluded that although the prognosis for PL is poor, the condition is survivable with aggressive intervention.[8] Furthermore, those who survive the neonatal period seem to eventually experience improvement of their disease.[4,8] Clearly a spectrum of severity exists. With further delineation of the molecular mechanisms controlling development of the lymphatic system, it is likely that new methods of classifying and ultimately treating PL will become available.

## Lymphangioma, Lymphangiomatosis, and Gorham-Stout Disease

Abnormal proliferation of lymphatic vessels distinguishes lymphangioma, lymphangiomatosis, and Gorham-Stout disease from other lymphatic disorders of the lung. Whereas lymphangioma refers to a solitary malformation, lymphangiomatosis refers to the presence of multiple lymphangiomas and is less common than the occurrence of a single lymphangioma. Gorham-Stout disease is a related syndrome characterized by chylothorax and bone cysts, with lymphangioma seen on biopsy.

Lymphangiomatosis is a severe disease characterized by the occurrence of numerous lymphangiomas, often affecting multiple organs. Involvement of the liver, soft tissue, spleen, bones, mediastinum, and lungs may occur.[2,9] The disease is reported more frequently in children than adults, and a significant percentage of these cases present during infancy.[9] Lymphangiomatosis involving the thorax can manifest in the mediastinum, pleural space, chest wall, lungs, or pericardium. Individuals with thoracic involvement may present with cough, chest pain, dyspnea, or wheezing.[9] Chylous effusions are often a prominent component of the clinical disease pattern of lymphangiomatosis.[2,9] Chest radiography reveals interstitial infiltrates, chest masses, effusions, or bone lesions.[2] In addition to multiple lymphangiomas, HRCT of the chest may exhibit smooth thickening of interlobular septa and bronchovascular bundles, ground-glass attenuation, or effusions.[9] Biopsies of lymphatic lesions are characterized by increased numbers of dilated lymphatic channels lined by endothelium.[2]

The natural history of lymphangiomatosis entails progressive growth of lymphangiomas, which eventually compress vital structures. Both young age and respiratory involvement predict a particularly poor outcome.[9] However, successfully treated cases of lymphangiomatosis with thoracic involvement have been reported.[10] Therapy for severely symptomatic pleural effusions may include thoracentesis or pleurodesis. When lymphangiomas are diffuse, complete surgical resection may not be possible. Medical therapy for lymphangiomatosis using sirolimus or interferon alpha-2b has been reported, with the aim of halting the lymphatic proliferation that is the hallmark of the disease.[10,11]

Gorham-Stout disease is characterized by the proliferation of vascular structures within bones, leading to osteolytic lesions evident on radiography.[12] Chylothorax is associated with the disease, possibly related to dysplasia of lymphatic vessels at the pleura.[12] Children are more commonly affected than adults, and presenting symptoms may include cough, dyspnea, and pain.[13] The presence of chylothorax is associated with worsened prognosis in this severe disease.[12] Similar to what is reported in lymphangiomatosis, there are case reports describing approaches to medical therapy.[12–14] Ongoing efforts to improve the classification and phenotyping of lymphatic dysplasias, including PL and lymphangiomatosis, may lead to improved diagnostic strategies, molecular understanding, and targeted therapeutic considerations. The Lymphangiomatosis and Gorham Disease Alliance advocates on behalf of patients and families and provides education and support (https://www.lgdalliance.org/).

## Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) is characterized by abnormal smooth muscle proliferation and cystic destruction in the lung. This disorder typically presents in women of childbearing age with recurrent pneumothoraces, progressive dyspnea, and/or multiple lung cysts evident on HRCT.[15] Although lymphatic involvement is not always a prominent feature, some patients may develop chylous effusion.[15] Despite the similar-sounding terminology, LAM is distinct from lymphangiomatosis and is differentiated based on the presence of lung cysts and distinct immunohistochemistry.[15] LAM may occur sporadically, without a known inheritance pattern, or it may be associated with tuberous sclerosis complex (TSC), an autosomal dominant disease with variable penetrance.[15] Rarely, cystic pulmonary disease can occur in children with TSC (Fig. 55.2).[16] Although at least 40% of adult women with TSC have lung cysts compatible with LAM, symptomatic pulmonary disease is rare in girls with TSC.[17–19] One study from a single referral center reported age-dependent risk of LAM in females with TSC, with a prevalence of 26% in females with TSC below 21 years of age and 81% in those above 40 years of age.[20] Consensus guidelines published in 2013 recommend LAM screening in females with TSC starting at age 18 years.[21] The Tuberous Sclerosis Alliance (www.tsalliance.org) and LAM Foundation (www.thelamfoundation.org) offer information, resources, and a worldwide network to those affected.

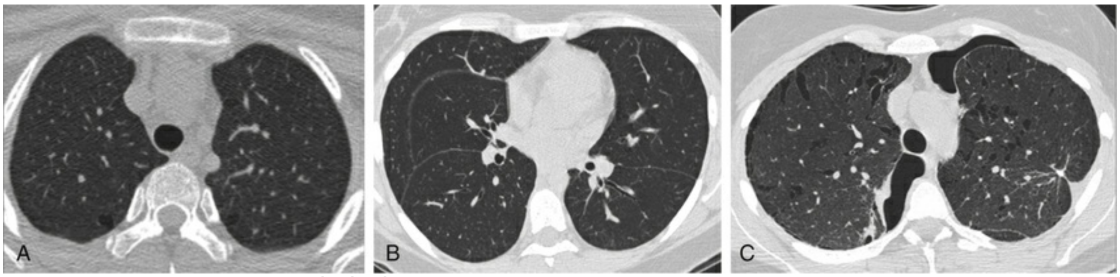

**FIG. 55.2** (A) Chest high-resolution computed tomography (c-HRCT) image from a 16-year-old female with tuberous sclerosis complex (TSC), showing a few radiolucent thin-walled cysts bilaterally. These findings, which are consistent with very mild early lymphangioleiomyomatosis, were detected on screening c-HRCT in this asymptomatic teenager. (B) c-HRCT demonstrates only a few tiny cysts in this 17-year-old female with TSC; however, she subsequently

experienced unusually rapid progression, including bilateral pneumothoraces. (C) Subsequent c-HRCT (age 18.5 years) shows diffuse cystic lung disease and residual bilateral pneumothoraces. (Case provided by Lisa R. Young, MD, Cincinnati Children's Hospital Medical Center.)

# Pulmonary Alveolar Microlithiasis

## Epidemiology

PAM is an autosomal recessive disease characterized by the deposition of calcium phosphate calculi within alveoli. Although the majority of reported cases of PAM historically describe adults, increased numbers of children with the disorder have been identified more recently. A few cases report diagnosis during infancy and early childhood.[22] Tachibana et al. report 52% of a series of 111 patients identified before the age of 15 in Japan.[23] In Turkey and Italy, the mean age of diagnosis was 27 and 30 years, respectively.[23]

## Etiology and Pathogenesis

A gene linked to PAM has been identified, and the cause of the disease has been linked to disordered phosphate transport in the alveolar space.[24] *SLC34A2* encodes a type IIb sodium-dependent phosphate transporter and is expressed in type II alveolar cells.[24] Mutations most often lead to a loss of function or premature termination.[22] One of the functions of type II alveolar cells involves degradation of surfactant. Phosphate is a waste product of this degradation and will build up in cells unless properly removed. Saito et al. showed that epithelial deletion of the SLC34A2 gene product NPT2b sodium-dependent phosphate cotransporter in mice results in a PAM phenotype.[24] Mice with this deletion develop microlith accumulation in alveoli, typical radiographic findings, and pulmonary fibrosis, strongly suggesting that dysfunction of NPT2b causes PAM.[24]

## Clinical Features

Individuals with PAM, especially in the pediatric population, are usually asymptomatic at the time of diagnosis.[23] Remarkably, this absence of symptoms occurs despite impressive radiologic changes evident on chest imaging. Mariotta et al. reviewed the literature to describe 576 cases of the disorder and reported the presence of symptoms (including dyspnea, cough, and chest pain) in only about half of those affected.[25]

Patients may also present with digital clubbing or, less commonly, pneumothorax.[22] The micronodules evident on chest radiography often appear denser at the lung bases and can obscure the borders of the cardiac silhouette and diaphragm.[23] HRCT may reveal micronodules, ground-glass opacities, subpleural interstitial thickening, and interlobular septal thickening.[22] In pediatric patients, ground-glass opacification can predominate over the nodular calcific densities classically ascribed to the disease in adults (Fig. 55.3).[26] At diagnosis, pulmonary function testing may be normal or show slightly decreased vital capacity or diffusing capacity.[23] Decline of pulmonary function and occurrence of respiratory insufficiency occur over decades.[23,25]

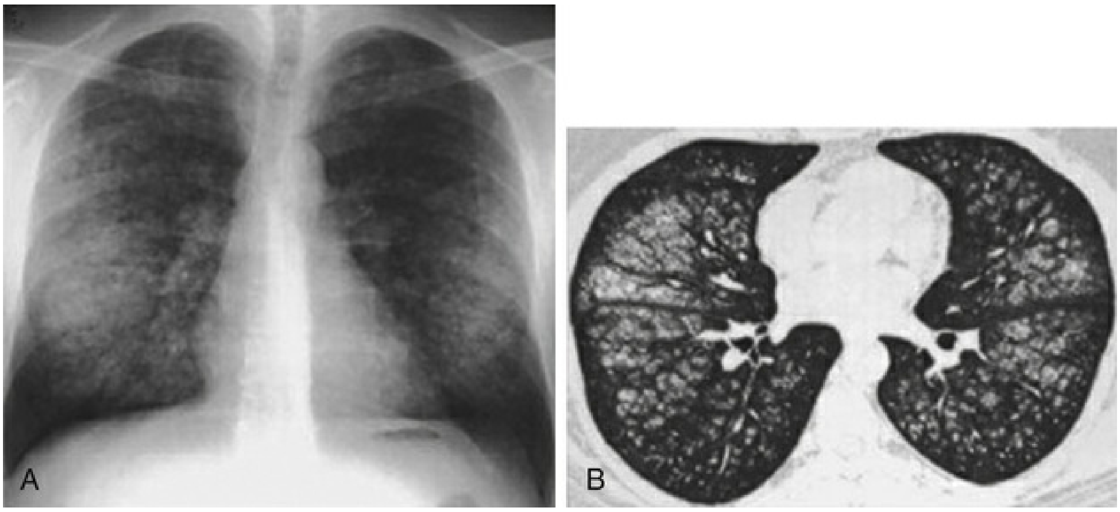

**FIG. 55.3** Radiographic features of pulmonary alveolar microlithiasis. (A) Posteroanterior chest radiograph showing the classic “sandstorm” appearance of pulmonary alveolar microlithiasis, including diffuse, patchy, bilateral sharp micronodular disease. (B) High-resolution computed tomographic scan of the chest showing micronodular densities. (From Brandenburg VM,

Schubert H. Images in clinical medicine. Pulmonary alveolar microlithiasis. *N Engl J Med*. 2003;348:1555.)

## Diagnosis and Differential Diagnosis

PAM is distinguished from other pulmonary diseases by its "sandstorm" appearance on plain chest film, representative of calcium-phosphate micronodules. This finding is considered by some to be pathognomonic for the disease. Sarcoidosis, tuberculosis, histoplasmosis, and idiopathic pulmonary hemosiderosis can be considered in the differential diagnosis.

## Management and Prognosis

PAM usually progresses, at varying rates, to pulmonary fibrosis, pulmonary hypertension, and respiratory failure over several decades following diagnosis.[22] Although various therapies have been tried, there is currently no cure for PAM. Corticosteroids and whole-lung lavage have not shown efficacy.[22] Lung transplantation has been performed successfully.[22] It is hoped that new therapies directed at correcting the disease-causing Npt2b-dependent phosphate transporter will halt or slow the formation of microliths and prevent the severe lung disease associated with PAM.

# Ataxia Telangiectasia

Ataxia telangiectasia (AT) is an autosomal recessive, progressive multisystem disorder caused by homozygous or compound heterozygous mutations in the gene ATM (ataxia-telangiectasia mutated; 11q22.3).[27] Disease manifestations occur in early childhood, with progressive cerebellar ataxia and later conjunctival telangiectases, progressive neurologic degeneration, immune deficiency, and malignancies. The molecular pathogenesis is complex but involves abnormal DNA damage responses leading to a high rate of intrachromosomal recombination and genomic instability. Respiratory manifestations include recurrent infections related to immunodeficiency, chronic aspiration due to swallowing dysfunction, ineffective airway clearance, and interstitial lung disease. Most patients die young of respiratory causes or malignancies, with a disparately higher mortality rate among African Americans historically.[28] As is true for most rare lung diseases, there are few controlled trials to guide management. The European Respiratory Society (ERS) recently published a thorough statement on the multidisciplinary management of the respiratory manifestations of AT.[29]

Immunodeficiency in AT is variable, with both humoral and cellular abnormalities. Patients with recurrent respiratory infections and poor vaccine responses are candidates for immunoglobulin replacement therapy. Immunodeficiency does not seem to progress over time in AT.[30] Bronchiectasis develops in many patients in the first decade of life. Neuromuscular involvement, discoordinated swallowing, and impaired mucociliary clearance should be evaluated and managed, as for many patients susceptible to these disorders. Lung function measurement can be challenging because of neurologic abnormalities but can be useful to define bronchodilator response and to monitor lung function over time. A recent study of children and young adults with AT demonstrated an inverse relationship between serum interleukin (IL)-6 levels and vital capacity, suggesting that systemic inflammation is correlated with lower lung function in AT, although the mechanism is uncertain.[31] In a large retrospective series, approximately one fourth of AT patients with chronic respiratory symptoms were found to have ILD, which has a unique histopathologic pattern and may be responsive to steroids if treated early in the course.[32] Because of the known cellular and chromosomal sensitivity to ionizing radiation in AT, effort should be made to limit diagnostic radiation as much as possible. A recent study showed that inspiratory muscle training improved ventilatory pattern, lung volume, respiratory muscle strength, and the health and vitality domains for quality of life in patients with AT.[33] A coordinated, multidisciplinary approach to monitoring and managing respiratory involvement in AT will likely result in improved respiratory health for these patients.

## Gaucher Disease

### Epidemiology, Etiology, and Pathobiology

The most common lysosomal storage disease, Gaucher disease is an autosomal recessive disorder caused by a mutation in the glucocerebrosidase gene, resulting in an abnormal buildup of glucocerebroside. This accumulates within macrophages and is identified pathologically as Gaucher or foam cells. In the lung, infiltration of Gaucher cells may occur within alveoli, interstitial spaces, around airways, or within pulmonary vasculature.[34,35]

## Clinical Features

Some patients with type 2 and type 3 Gaucher disease display a pattern of alveolar consolidation related to Gaucher cells, whereas others manifest a pattern of interstitial disease with associated fibrosis, usually seen in type 3 disease.[36] In addition to parenchymal lung disease, type 1 Gaucher disease may be complicated by pulmonary vascular disease, including pulmonary arterial hypertension and hepatopulmonary syndrome.[36] Although clinical pulmonary disease is uncommon, a significant number of patients have abnormal pulmonary function testing.[37] Chest radiography may display reticulonodular changes, and HRCT shows ground-glass consolidation, interstitial involvement, alveolar opacities and bronchial wall thickening (Fig. 55.4).[38]

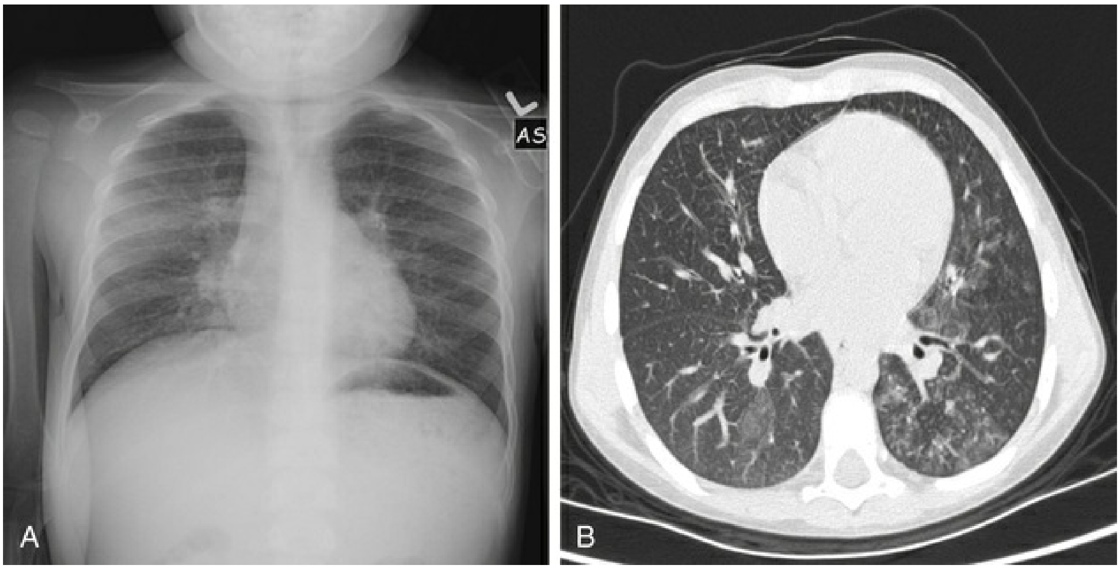

**FIG. 55.4** (A) Chest radiograph of a 3-year-old female with Gaucher disease who had received enzyme replacement therapy since infancy reveals

reticulonodular changes and areas of consolidation. (B) Computed tomography of the chest with mosaic pattern and areas of septal thickening. Bronchoalveolar lavage revealed numerous foam cells *(not pictured).* (Images provided by Roberta Kato, MD, Children's Hospital, Los Angeles.)

## Management, Treatment, and Prognosis

Whereas enzyme replacement therapy for Gaucher disease decreases organomegaly and improves hematologic parameters, it may not reverse severe pulmonary parenchymal disease.[34] However, this therapy may in some cases slow or prevent a progressive decline in lung function.[35,39] Most cases of clinically significant pulmonary vascular disease have been described in adults.[36] The severity of pulmonary arterial hypertension does not correlate with the severity of Gaucher disease in other organ systems and may improve or stabilize with the initiation of enzyme replacement therapy and medical therapy for pulmonary hypertension.[36] Hepatopulmonary syndrome in Gaucher disease is associated with more severe liver disease and also may improve with the initiation of enzyme replacement therapy.[36] The National Gaucher Foundation (www.gaucherdisease.org) seeks treatments and a cure for Gaucher disease.

# Niemann-Pick Disease

## Epidemiology, Etiology, and Pathobiology

Niemann-Pick disease (NPD) is a rare, autosomal recessive lysosomal storage disorder characterized by a deficiency of acid sphingomyelinase, leading to the accumulation of sphingomyelin within cells and tissues. In the lung, buildup of foam cells containing sphingomyelin occurs within alveoli, alveolar walls, lymphatic spaces, and the pleural space.[40]

## Clinical Features

Whereas type A NPD manifests as a severe neurodegenerative disorder, individuals with type B NPD have little or no neurologic involvement and often survive into adulthood.[41] Pediatric patients with type B NPD present with hepatomegaly, splenomegaly, thrombocytopenia, and dyslipidemia. Respiratory involvement can be seen in all forms of NPD but has been seen most frequently in type B.[41] Individuals may present with recurrent cough, exercise intolerance, or recurrent respiratory infections.[41] Pulmonary function abnormalities are common and are characterized by decreased FVC, $FEV_1$, and diffusing capacity.[42]

A significant number of individuals with type B NPD exhibit chest imaging and lung histopathology consistent with interstitial lung disease (ILD).[42] Rarely, a severe form of ILD due to NPD may present in infancy or early childhood. Radiographic abnormalities of HRCT observed in NPD include ground-glass appearance, reticulonodular densities, thickening of interlobular septa, and a crazy-paving pattern.[41,42] The severity of radiologic findings has not been found to correlate with pulmonary function testing.[41,42] Bronchoalveolar lavage is characterized by Niemann–Pick cells, which appear as multivacuolated histiocytes with blue-staining granules.[41] Histopathology shows infiltration of the interstitium, alveoli, lymphatics, and subpleural space.[41]

## Management, Treatment, and Prognosis

Although no specific treatment for NPD exists, research into bone marrow transplantation, enzyme replacement therapy, and gene therapy is ongoing. Whole-lung lavage has been tried for the most severe cases, with varying success.[40] In many cases ILD is indolent and associated with survival well into adulthood.[41] However, some cases of ILD due to NPD can be rapidly progressive and lead to respiratory failure during childhood.[41] It is hoped that therapies aimed at correction of the underlying disease will contribute to stabilization or improvement of lung disease associated with NPD. The National NPD Foundation (www.nnpdf.org) provides support services for individuals and families affected by the disorder.

# Neurofibromatosis

Neurofibromatosis type 1 (NF-1) is an autosomal dominant disorder characterized by neurofibromata, café au lait spots, pigmented hamartomas of the iris, skeletal dysplasia, and optic glioma. Thoracic involvement in NF-1 mainly entails the presence of neurofibromata, often plexiform, that may arise from the chest wall or posterior mediastinum (Fig. 55.5).[42] Plexiform neurofibromata have multiple nerve roots and can surround vital structures, making resection complex.[43] As malignant transformation may occur, biopsy of these masses should be considered.[43] In addition to tumors and bony abnormalities affecting the thorax, NF-1 is also associated with ILD.[44] The ILD associated with NF-1 appears radiographically as large, apical thin-walled bullae and basilar fibrosis.[44] Diffuse lung disease associated with neurofibromatosis mainly occurs in adult patients and has not yet been reported in children.[44] The Children's Tumor Foundation (www.ctf.org) is dedicated to improving the health and well-being of individuals and families affected by NF.

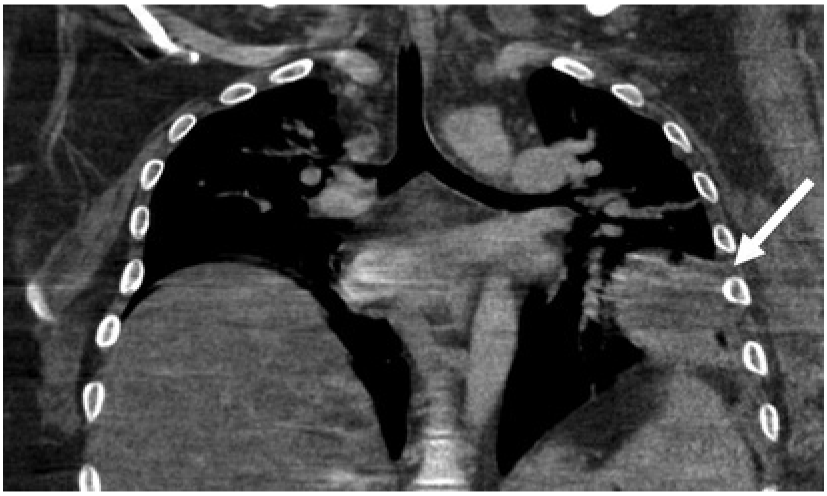

**FIG. 55.5** Computed tomography sagittal section of a 21-year-old with neurofibromatosis type I, demonstrating a soft tissue mass abutting the left chest wall with adjacent atelectasis. Biopsy of the mass was consistent with neurofibroma.

# Dyskeratosis Congenita

Dyskeratosis congenita (DC) is a form of ectodermal dysplasia characterized by skin hyperpigmentation, nail dystrophy, oral leukoplakia, and bone marrow failure.[45,46] A number of mutations in genes coding for proteins that function to maintain telomeres have been identified in patients with DC.[45] Whereas a minority of those with DC manifest pulmonary involvement such as fibrosis, the disease can have significant morbidity (Fig. 55.6).[46] Owing to the high percentage of children with DC receiving bone marrow transplants, characterization of the etiology of lung disease when it occurs after transplant can be difficult. However, a number of pulmonary complications, including pulmonary fibrosis and hepatopulmonary syndrome, have been described after bone marrow transplantation.[46–48] Therefore it is likely that at least in some cases, development of pulmonary fibrosis is either due to or exacerbated by the telomerase dysfunction known to occur in DC.[48]

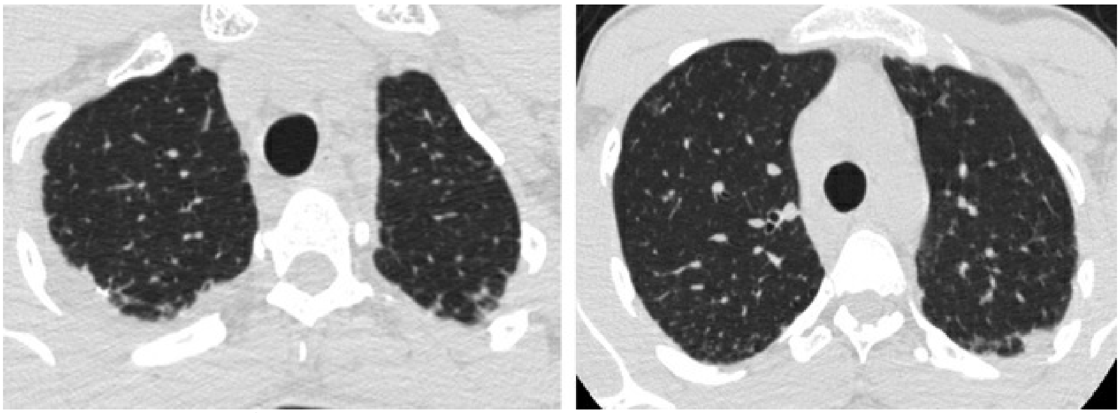

**FIG. 55.6** Chest high-resolution computed tomography images demonstrating subpleural-predominant thickening of the secondary interlobular septa, consistent with early pulmonary fibrosis in this 18-year-old patient with dyskeratosis congenita. (Case provided by Lisa R. Young, MD, and Ronald Bokulic, DO, Cincinnati Children's Hospital Medical Center.)

# Hermansky-Pudlak Syndrome

Hermansky-Pudlak syndrome (HPS) is an autosomal recessive disorder characterized by oculocutaneous albinism, bleeding diathesis, and pulmonary fibrosis.[49] Notably, the disease has an especially high prevalence in a section of Puerto Rico. The underlying disorder in HPS involves disturbed formation or trafficking of intracellular vesicles. This perturbation results in dysfunction of lysosome-related organelles within a number of cell types, including macrophages and type II pneumocytes.[50,51] Clinically, lung disease has been reported only in individuals with subtypes HPS-1, HPS-2, and HPS-4; it usually manifests in the third or fourth decades of life, although pediatric onset has been reported.[51–53] Pulmonary function testing reveals restrictive lung disease, and HRCT indicates pulmonary fibrosis.[53] Disease may progress to death in the fourth or fifth decade of life.[53] Lung transplantation has been successfully performed in a number of individuals with HPS, although consultation with a hematologist is advised to assist in the management of potential bleeding complications. The HPS Network (www.hpsnetwork.org) is a support group for people and families dealing with the disorder. Ongoing investigation of the cellular mechanisms responsible for disease as well as medications targeted against pulmonary fibrosis will contribute significantly to the care of patients with HPS.

## Alpha-1 Antitrypsin Deficiency

Although alpha-1 antitrypsin (ATT) deficiency is not a rare disorder per se, pulmonary manifestations of AAT deficiency occur very rarely, if ever, in children. Familiarity with the disorder is of value to pediatric pulmonologists since pediatric practitioners are responsible for educating patients and families regarding genetic testing and providing anticipatory guidance for those who carry the diagnosis.

### Epidemiology

AAT deficiency is one of the most common inherited diseases worldwide, and its diagnosis often goes delayed or unrecognized.[54] It is estimated that only about 5% of individuals in the United

States with the disorder are actually diagnosed.[55] AAT deficiency is inherited in a codominant manner, and over 100 variants of the AAT protein have been identified. Various AAT phenotypes are associated with different levels of the protein, and the serum level of AAT determines the risk of emphysema. The PiZZ genotype is the most prevalent disease, causing phenotype in populations of Northern European descent.[56]

Much of the available knowledge regarding the epidemiology of AAT deficiency in children stems from a birth cohort that identified 184 individuals in Sweden, where AAT screening of 200,000 newborns occurred from 1972 to 1974.[57] These studies found lung function testing to be normal in adolescents up to age 18 with PiZZ.[57] However, when compared with those who do not smoke, Piitulainen and Sveger (1998) found 18-year-olds with either PiZZ or PiSZ genotypes who smoked to have a lower $FEV_1$ and $FEV_1/FVC$.[57] Thus the authors concluded that the first signs of lung disease in AAT-deficient smokers occur in adolescence.[57] At the age of 22 years, pulmonary function testing, although still within the normal range (mean $FEV_1$ 98% predicted), was found to have significantly declined (mean 1.2% annual decline) when compared with testing done at 16 and 18 years.[58] Furthermore, 29% of individuals reported wheezing and 15% had been diagnosed with asthma.[58] Thus the authors speculated that respiratory symptoms in young adults with PiZZ may be misidentified as asthma, contributing to a delay in diagnosis for those with symptoms of AAT deficiency.[58] Exposure to environmental tobacco smoke during childhood has also been associated with an earlier onset of symptoms.[59] Families of children with AAT deficiency will benefit from anticipatory guidance regarding the dangers of exposure to tobacco smoke.

## Etiology and Pathobiology

AAT inhibits the activity of a number of proteolytic enzymes, the most important of which is neutrophil elastase.[54] Lung disease in AAT deficiency occurs primarily secondary to loss of function, resulting in an imbalance between levels of AAT relative to the amount of neutrophil elastase. Neutrophil elastase degrades elastin and extracellular matrix elements located within the lower respiratory tract that normally function to maintain the structural integrity of the lung.[56]

Considering that not all at-risk individuals develop disease, other environmental and genetic components modulate the development of emphysema. For instance, a relationship between smoking, AAT deficiency, and the development of emphysema has been well established. In addition to cigarette smoking, exposure to kerosene heaters, employment in agriculture, and exposure to other pollutants from biomass fuel sources have all been implicated in the development of emphysema.[55,56]

## Clinical Features

It should be emphasized that AAT deficiency has not been shown to cause clinical lung disease in the pediatric population. The vast majority of children with AAT deficiency present with liver disease. The mean age of presentation of lung disease in AAT deficiency is 32 to 41 years, and presentation before 25 years is rare.[56] Relatively early onset of symptoms usually occurs in smokers or those with a history of smoking. In addition to liver disease, AAT deficiency has also been associated with bronchiectasis, necrotizing panniculitis and multisystem vasculitis.[56]

## Diagnosis

Decreased serum levels of AAT indicate disease and necessitate further workup. Genotyping by polymerase chain reaction (PCR) or isoelectric focusing (phenotyping) identify AAT variants and are used to confirm the diagnosis.[56]

Predispositional testing, or the testing of asymptomatic individuals at risk for developing disease, has relevance to the pediatric population. Concerns exist regarding the psychological ramifications of being diagnosed during childhood with a disease that may not manifest for decades, if at all.[55,56] It has been speculated that knowledge of the illness may have a negative impact on a child's self-image or relationship with family members and peers.[56] Furthermore, concerns exist regarding the ability to secure health insurance and employment.[55] However, pediatric patients diagnosed with AAT deficiency can be counseled against tobacco use and the dangers of other relevant environmental exposures, and such counseling may be more effective when initiated at a younger age.[55,56]

Guidelines recommend testing of siblings of an individual with AAT deficiency, and genetic testing should be discussed for siblings of an individual who is heterozygous.[56] It is recommended that the genetic testing of adolescents proceed only if the adolescent is sufficiently mature to understand the issues involved in testing and that both assent and parental permission have been obtained.[56]

## Management and Treatment

Treatment of respiratory manifestations of AAT deficiency centers on therapy for airways obstruction and hypoxemia, antimicrobials for secondary infection, and replacement enzyme (augmentation) therapy.[56] Although the benefit and cost-effectiveness of augmentation therapy remain controversial, many experts recommend treatment for selected individuals.[54,56] Future therapies seek to address the misfolding of AAT or use small fragment homologous replacement therapy to correct the gene defect of AAT deficiency.[54] The Alpha-1 Association (www.alpha1.org) and Alpha-1 Foundation (www.alpha-1foundation.org) provide resources, support, education, and advocacy.

# Summary

Rare lung disorders influence the care of children with respiratory diseases in a number of fundamental ways. Understanding of normal biologic function is often facilitated via characterization of the disrupted pathways occurring in rare diseases. This knowledge can then be applied to related diseases that occur with higher prevalence. Most importantly, the respiratory practitioner's ability to identify and care for pediatric patients with diseases that occur uncommonly will have a significant impact on the lives of those affected.

# Childhood Interstitial Lung Disease Disorders More Prevalent in Infancy

*Lisa R. Young MD, Gail H. Deutsch MD*

## Overview

While there are areas of overlap, childhood interstitial lung diseases (ILD) frequently include differing entities and histologic patterns than those described in adult ILD. The areas of distinction are particularly apparent for ILD in infants and young children; therefore this chapter reviews specific forms of childhood ILD that are "more prevalent in infancy."

One factor prompting the need for distinct consideration of childhood ILD in infants is that prominent case clustering occurs in infancy. In a series reported by Fan et al., the median age of onset was 8 months.[1] Two subsequent large multicenter studies have also shown a predominance of cases in young children. In the European Respiratory Society task force survey of chronic ILD, children under age 2 years comprised 31% of cases.[2] Because this study's inclusion criteria required symptom duration of at least 3 months, neonates with a rapidly progressive course would have been excluded, and the proportion of cases in young children is likely underestimated. In studies utilizing lung biopsy ascertainment, the Children's Interstitial Lung Disease Research Network (ChILDRN) has identified that approximately 50% of lung biopsies for diffuse lung disease are performed in children less than 2 years of age.[3,4] Furthermore, within the cohort of young children, infants represent a large proportion of cases. Of 187 cases reviewed in the ChILDRN infant study, 30% underwent biopsy by 3 months of age and 52% underwent biopsy by 6 months of age.[3]

As detailed in a 2013 American Thoracic Society Clinical Practice Guideline, it is useful to separately consider the clinical differential diagnosis of ILD in an infant versus an older child.[5] Certain entities are either not seen in older children or clearly have symptom onset in infancy. Finally, there is high variability in morbidity and mortality associated with infant ILD disorders, emphasizing the critical need for accurate diagnosis. This chapter highlights several disorders that present in infancy or within the first year of life, including Alveolar Capillary Dysplasia with Misalignment of Pulmonary Veins (ACDMPV), Pulmonary Interstitial Glycogenosis (PIG), and Neuroendocrine Cell Hyperplasia of Infancy (NEHI). Additionally, while bronchopulmonary dysplasia is discussed in Chapter 20, lung growth abnormalities are included in this chapter, because they manifest in infancy and their clinical and radiographic presentation frequently overlaps with other forms of infant ILD. Disorders of surfactant production and homeostasis, more prevalent in infancy but also present in older children, are discussed separately in Chapter 57.

# Alveolar Capillary Dysplasia With Misalignment of Pulmonary Veins

## Epidemiology

Alveolar capillary dysplasia with ACDMPV is a rare and generally lethal developmental disorder of the lung that typically causes very early postnatal respiratory distress.[6,7] The disorder is named based on distinctive abnormalities of the pulmonary vasculature and is also variably termed *alveolar capillary dysplasia* and *congenital alveolar capillary dysplasia*. As definitive diagnosis currently depends on histologic examination of the lung on biopsy or at autopsy, the true prevalence is unknown; over 200 cases of ACDMPV have been reported in the literature to date. While the majority of cases are sporadic, approximately 10% are familial with affected siblings,[8–12] and no sex predilection has been identified.

## Etiology and Pathogenesis

Heterozygous inactivating point mutations and microdeletions involving *FOXF1* and its upstream interval on chromosome 16q24.1 have been found in a large number (~50%) of sporadic and familial cases of ACDMPV and concurrent anomalies.[8,13] Among deletions in which parental origin can be determined, all arose de novo on the maternal chromosome consistent with *FOXF1* being paternally imprinted.[12,14,15] The ability to noninvasively test for this gene has recently uncovered that patients with *FOXF1* mutations can have a variable phenotype, including milder symptoms with long-term survival.[16,17] This variability may be because of somatic mosaicism, partial imprinting, or modifier genes.[17] The frequently associated cardiac and gastrointestinal anomalies in patients with ACDMPV are thought to be due to haploinsufficiency for the neighboring FOXC2 and FOXL1 genes in the Forkhead box (FOX) transcription gene cluster.[13]

*FOXF1* in mice is regulated by hedgehog and bone morphogenetic protein (BMP) signaling and encodes a transcription factor expressed in the lung mesenchyme and involved in murine vasculogenesis and lung development.[18,19] Mice with reduced levels of pulmonary Foxf1 die of pulmonary hemorrhage with deficient alveolarization and vasculogenesis, but they do not have malposition of pulmonary veins.

Mechanisms linking the abnormal lung vasculature with severe hypoxemia and pulmonary hypertension in ACDMPV remain to be fully explained. It is currently unclear whether the prominent arterial and lobular abnormalities in this disorder are primary or secondary to the vein misalignment. Medial hypertrophy of small pulmonary arteries may result from deficient lobular development with poor gas exchange and resultant hypoxemia, and intrapulmonary right-to-left shunts through bronchial veins have been demonstrated by three-dimensional image reconstruction of lung from infants who died from ACDMPV.[20]

## Clinical Features and Presentation

Infants with ACDMPV are usually born at term, and, in the majority of cases, the onset of cyanosis and respiratory failure occurs within 48 hours after birth.[10] Delayed onset by weeks or even months has been described rarely, but this is becoming more recognized as genetic testing for *FOXF1* mutations and deletions are now available.[21–24] The initial presentation is indistinguishable from persistent pulmonary hypertension of the newborn, and echocardiogram typically demonstrates suprasystemic right ventricular pressures and right-to-left shunting through a patent ductus arteriosus or patent foramen ovale. Approximately 80% infants with ACDMPV have additional malformations with cardiac (commonly hypoplastic left heart), gastrointestinal (intestinal malrotation and atresias), and renal abnormalities (hydronephrosis) being the most frequent.[11,13,25,26]

# Radiologic Findings

The initial chest radiograph is often normal with subsequent development of diffuse hazy opacities, and the findings are also dependent on concurrent anomalies. Pneumothoraces are frequently reported, which may be a consequence of abnormal lung architecture or aggressive ventilation. Computed tomography (CT) or magnetic resonance lung imaging of patients with lethal ACDMPV have not been described, although a long-term survivor (36 months) had bilateral widespread ground glass opacities with relatively less affected areas on chest CT.[16]

## Histologic Findings

ACDMPV is defined by a characteristic constellation of features, of which anomalously situated pulmonary veins running alongside small pulmonary arteries is essential (Fig. 56.1A–D).[3] Normally, pulmonary veins are in the interlobular septa, arising from small veins that drain pulmonary lobules. In addition to aberrant placement of the veins in ACDMPV, there is reduction or absence of veins in interlobular septa. Muscularization of small pulmonary arteries and arterioles is often striking, and there is reduced capillary density in alveolar walls (see Fig. 56.1E and F). Simplification of the lobular architecture with lymphangiectasia is variably present.

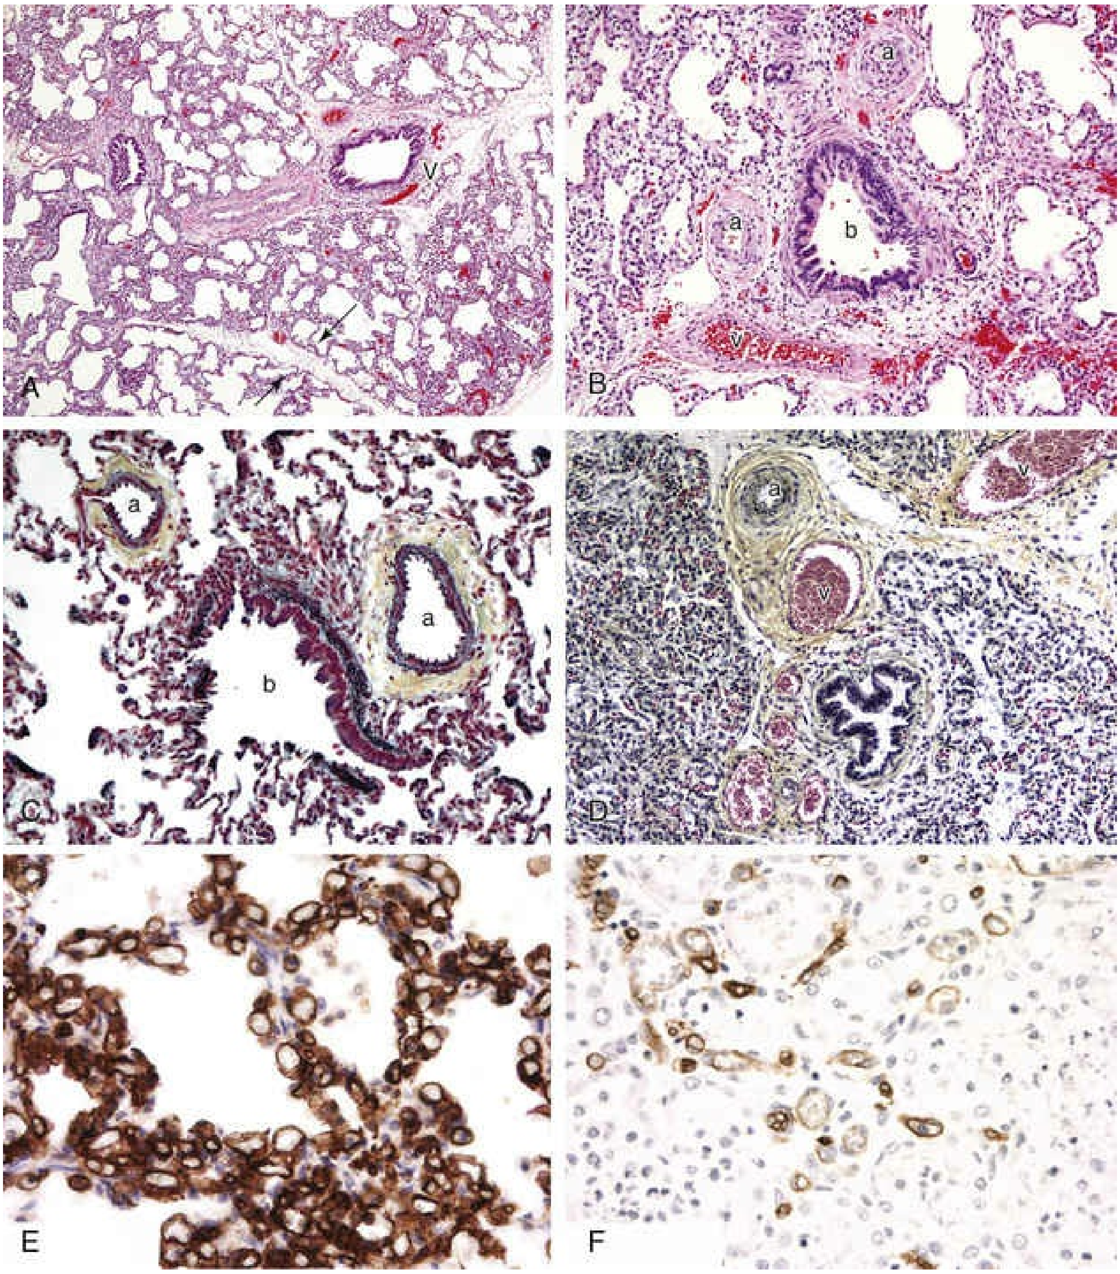

**FIG. 56.1** Alveolar capillary dysplasia with

misalignment of pulmonary veins. (A, B, and D) Pulmonary veins (v), which are normally in the interlobular septa *(arrowheads),* are malpositioned and accompany pulmonary arteries (a) and bronchioles (b). There is lobular maldevelopment with no alveoli and interstitial widening (A, H&E, ×40); (B, H&E, ×100); (D, 10×, Movat pentachrome stain). (C) Normal airway for comparison (Movat pentachrome stain, original magnification 100×). (E and F) The marked decrease in alveolar wall capillaries is highlighted by the endothelial cell marker CD31 (×400).

## Diagnosis and Differential Diagnosis

The diagnosis of ACDMPV should be considered in infants who present with severe hypoxemia and pulmonary hypertension for which no anatomical cause can be established. Historically lung biopsy or autopsy was required to confirm the diagnosis. Currently, genetic testing for disruption of FOXF1 may obviate the need for a tissue diagnosis. On histologic examination, the characteristic constellation of findings may be subtle, particularly when the lung sample is limited with few bronchovascular bundles for evaluation. Patchy distribution has rarely been reported,[24] and multiple lung sections may be required for confirmation.

The presentation of ACDMPV with persistent pulmonary hypertension of the newborn overlaps with other etiologies of severe idiopathic neonatal lung disease, including genetic abnormalities in surfactant metabolism (particularly *SFTPB and ABCA3 mutations*), diffuse PIG, and lymphangiectasia. Histologically, ACDMPV should be distinguished from other disorders that demonstrate a similar arrest in lung development, including congenital alveolar dysplasia and advanced pulmonary hypoplasia. While these disorders also demonstrate lobular simplification and frequently vascular changes (hypertensive changes of the pulmonary arteries and reduced capillary density within alveolar walls), they do not have malpositioned veins in the lobules.

## Management and Treatment

Standard therapy is supportive and includes mechanical ventilation, inhaled nitric oxide, and extracorporeal membrane oxygenation (ECMO). These therapies prolong life by days to weeks but have rarely led to long-term survival, and lung transplantation has rarely been attempted.

## Prognosis

Historically initial presentation of ACDMPV in the neonatal period denoted a grim prognosis. However, variable phenotypes and longer survival are now increasingly reported. The clinical presentation should be considered in determining on a case-by-case basis.

# Lung Growth Abnormalities Presenting as Childhood Interstitial Lung Diseases

## Epidemiology

The epidemiology of lung growth abnormalities is best considered in the context of their associated conditions including prematurity, oligohydramnios, congenital heart disease, and Trisomy 21. While only a small portion of cases undergo lung biopsy, it is important to acknowledge that lung growth abnormalities are a principal cause of diffuse lung disease in young children that prompts surgical lung biopsy. In the ChILDRN study, lung growth abnormalities represented the primary diagnostic category, with 25% of lung biopsies from children less than age 2 being classified in this category. Furthermore, this was the leading diagnostic category for five of the eleven participating centers.[3]

## Etiology and Pathogenesis

Lung growth is a continual process that occurs well into the postnatal period. As such both prenatal and postnatal insults can impact lung maturation and growth. Distension of the lung with liquid and fetal respiratory movements is required for normal fetal lung growth, so any mechanism that interferes with these processes can result in a prenatal growth disorder. Prenatal onset pulmonary hypoplasia ranges from mild to severe, depending on the mechanism of hypoplasia and timing of the insult in relation to the stage of lung development. Early insults that occur before 16 weeks gestation (renal anomalies, congenital diaphragmatic hernia) may interfere with airway branching as well as acinar development, while later events (premature rupture of membranes) will exclusively impact acinar development. Postnatal onset growth abnormalities impact late alveolarization, most evident in the subpleural space. Multiple factors likely lead to deficient alveolarization in infants with congenital heart disease, including hypoxia and abnormal pulmonary blood flow.

In addition to chromosomal disorders, single gene disorders are also associated with abnormal lung growth, particularly deficient alveolarization. For example, while mutations or deletions in *NKX2.1* may present with a phenotype of surfactant dysfunction, alveolar simplification may be the predominant finding.[27] Mutations in *FLNA* (filamin A), which cause X-linked periventricular nodular heterotopia, have also been associated with severe diffuse lung disease with alveolar simplification, lung cysts, and pulmonary hypertension.[28–31]

## Clinical Features and Presentation

While not traditionally considered a classic form of ILD, abnormalities of lung growth represent a prominent proportion of cases that undergo lung biopsy to define the nature of the diffuse lung disease.[3] Furthermore, the features of tachypnea, retractions, hypoxemia, and often diffuse radiologic abnormalities overlap with other forms of childhood ILD.

Although lung growth abnormalities are traditionally considered in the context of prematurity and prenatal onset pulmonary hypoplasia, they also occur in the setting of congenital heart disease, chromosomal abnormalities (particularly Trisomy 21), and in otherwise normal-term infants with early postnatal lung injury

(Table 56.1). While difficult to objectively define, most infants diagnosed with lung growth abnormalities by lung biopsy were reported to have clinical severity deemed out of proportion to their known comorbidities or circumstances.[3] In other words, typically an additional form of ILD is suspected, leading to the decision to pursue surgical lung biopsy in these patients.

**Table 56.1**

**Conditions Associated With Deficient Lung Growth**

| Factors limiting prenatal lung growth |
|---|
| ▪ Oligohydramnios (e.g., premature rupture of membranes, bladder outlet obstruction) |
| ▪ Restriction of thoracic volume from space-occupying lesions or thoracic deformities |
| ▪ CNS, neuromuscular disorders and other agents resulting in decreased fetal breathing |
| Prematurity-related chronic lung disease (classically termed *bronchopulmonary dysplasia*) |
| Congenital heart disease |
| ▪ Disorders with poor pulmonary blood flow (e.g., tetralogy of Fallot) |
| ▪ Cyanotic heart disease impairing postnatal alveolarization |
| Genetic defects |
| ▪ Trisomy 21 with deficient postnatal alveolarization |
| ▪ Other chromosomal abnormalities |
| ▪ *Nkx2.1* disruption |
| ▪ *FLNA* disruption |

## Radiologic Findings

Radiologic findings are variable based on the etiology, age of the infant, and severity of the growth abnormality (Fig. 56.2). Subpleural cysts may be present and are frequently seen in pulmonary hypoplasia associated with Down's syndrome.[32]

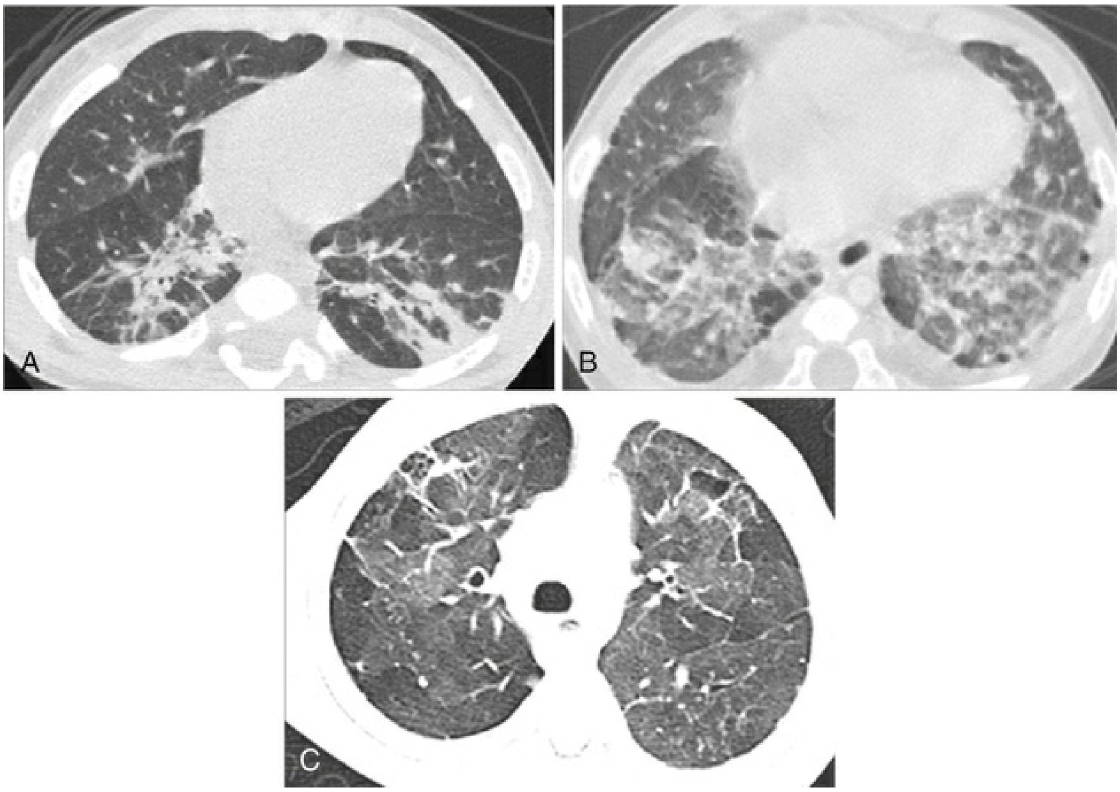

**FIG. 56.2** Imaging appearance of lung growth abnormalities. (A) Chest HRCT from a 22-month-old shows thickened irregular scarlike densities bilaterally, most pronounced in the lower lobes. Other findings (not shown) included mild airspace consolidation, mild air-trapping, and peribronchial cuffing without definite bronchiectasis. These findings were felt consistent with bronchopulmonary dysplasia in this former 27-week preterm infant with a history of prolonged need for ventilatory support. (B) Chest HRCT from a 5-month-old, former 32-week preterm infant with Trisomy 21 and AV canal shows diffuse irregular opacities, architectural distortion, septal thickening, and numerous small subpleural cysts. (C) Chest HRCT from a 3-year-old former 30-week preterm infant shows mosaic appearance with irregular ground-glass opacities and geometric areas of hyperlucency, which are predominately peripheral in location and consistent with dilated secondary pulmonary lobules. Other findings included scattered small cysts, few dilated bronchi, and air-trapping on the expiratory images (not shown).

## Histologic Findings

The ratio of lung weight to body weight is the most reliable parameter of lung growth, especially in preterm infants.[33,34] Obviously, this criterion is not useful for lung biopsies; therefore microscopic criteria are employed. The simplest method is the radial alveolar count, which is the number of alveoli transected by a perpendicular line drawn from the center of a respiratory bronchiole to the nearest septal division or pleural margin. The radial alveolar count in a full-term infant should average five alveolar spaces. While a valuable tool to evaluate lung complexity and growth, this method requires standardized inflation of the lung, as the radial alveolar count is substantially reduced in uninflated lungs.[35,36] In prenatal onset pulmonary hypoplasia, there is a reduction of number of alveolar spaces for gestational age, which is often accompanied by prominence of the bronchovascular structures and a widened interstitium. Lobular simplification with alveolar enlargement, often accentuated in the subpleural space, characterizes deficient alveolarization of postnatal onset (Fig. 56.3A and B). Following the widespread use of surfactant replacement and other therapies, the histology of “new bronchopulmonary dysplasia (BPD)”/chronic neonatal lung disease is characterized by less fibrosis and more uniform inflation than the classic form of BPD.[37] Hypertensive changes of the pulmonary arteries are commonly seen and are especially prominent in infants with a severe lung growth abnormality or Trisomy 21 (see Fig. 56.3C).[3,38] As discussed below, PIG is a frequent histologic finding in biopsies demonstrating impaired lung growth.

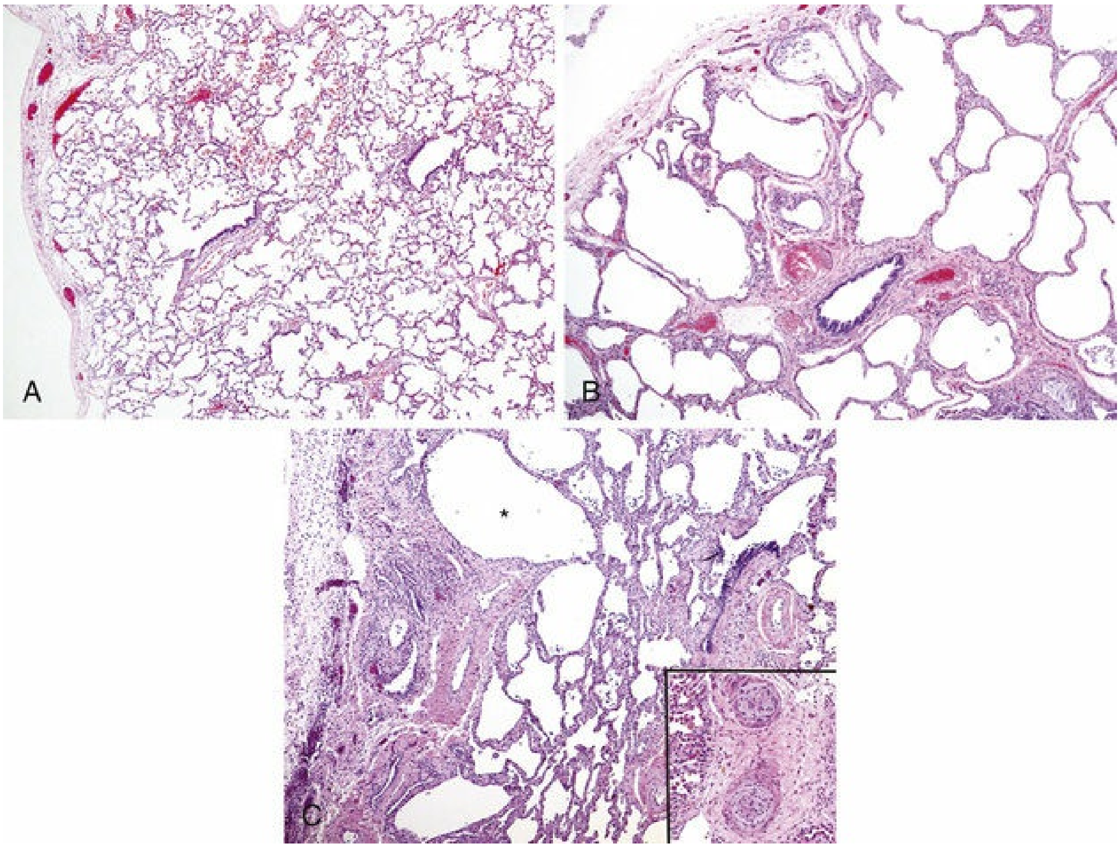

**FIG. 56.3** Abnormal lung growth. Lung biopsy from a 3-year-old former 32 week preterm infant (B) (H&E, ×40) demonstrates the characteristic abnormalities of impaired postnatal alveolarization, with reduced and markedly enlarged airspaces; compare with a normal-term infant at the same magnification (A). In Down syndrome (C) deficient lung growth is often most prominent in the subpleural space with cystic dilatation of alveoli *(asterisk)* and often accompanied by prominent hypertensive changes of the pulmonary vasculature *(inset).*

## Diagnosis and Differential Diagnosis

Clinical context provides high pretest probability of this diagnosis, and consideration of the clinical setting may obviate the need for lung biopsy in many cases. Infant pulmonary function tests may suggest pulmonary hypoplasia, but they do not exclude concurrent processes. For infants with respiratory morbidity out of proportion to their clinical context, lung biopsy may still be required for diagnosis and to exclude alternative diagnoses. Proper tissue handling is essential, and expert pathologic review may be required.[39]

The clinical differential diagnosis is broad and may include other abnormalities in lung development such as lymphangiectasia, ACDMPV, PIG, and genetic disorders of surfactant production and metabolism. From a pathology perspective, the presence of alveolar enlargement and simplification is often misinterpreted as emphysematous change or a consequence of lung remodeling after injury. However, in lung growth abnormalities, there is no evidence of a destructive process in a lung growth abnormality. Without proper orientation and handling, alveolar simplification may be overlooked or difficult to recognize. Indeed, in the ChILDRN study, the majority of lung growth abnormality cases were not suspected clinically or recognized histologically at the initial institution, especially when occurring outside the setting of prematurity.[3]

## Management and Treatment

Management is focused largely on supportive care and underlying conditions. Recognition of this category of diagnosis may have important clinical implications, particularly as corticosteroids may not be indicated in this setting.

## Prognosis

Lung growth and maturation are key determinants of postnatal outcome, especially in premature infants or those with chromosomal or congenital abnormalities. Lung growth abnormalities are associated with considerable morbidity and mortality when compared to other causes of diffuse lung disease. In the ChILDRN study, mortality was 34% for lung growth abnormality cases, a proportion similar to the entire study cohort. However, among lung growth abnormality cases, prematurity and pulmonary hypertension were independent clinical predictors of mortality. On lung biopsy, severe lung growth abnormality, as judged by degree of alveolar enlargement and simplification, was associated with a high mortality (80%).[3]

# Pulmonary Interstitial Glycogenosis

## Epidemiology

PIG is a form of childhood ILD unique to neonates and young infants.[3,40] Although the incidence and prevalence of PIG are unknown and it is rare, PIG occurs more frequently and in a broader clinical spectrum than previously recognized.

## Etiology and Pathogenesis

The etiology of PIG is incompletely understood, although clearly related to lung development. Expert pathologic review of lung biopsies from the multiinstitutional ChILDRN study found that patchy PIG was present in over 40% of cases classified as having a lung growth abnormality.[3] This included not only chronic neonatal lung disease due to prematurity but also pulmonary hypoplasia and lung growth abnormalities in the setting of Trisomy 21 and congenital heart disease. Patchy PIG was also present in 22% of cases classified as vascular disorders masquerading as ILD.[3] Published and personal experience indicates that it is very unusual to observe PIG in lung biopsies beyond 6 months of age.

In their original report, Canakis and colleagues speculated that PIG reflects a delay or aberration in the maturation of pulmonary mesenchymal cells that do not normally contain abundant glycogen.[40] Others have suggested that PIG might reflect a nonspecific feature of several conditions that transiently alter lung growth and development in the neonatal period.[41] Recently, the presence of interstitial lipofibroblasts, cells reportedly seen only during prenatal lung development, were demonstrated in PIG biopsies.[42] Pulmonary lipofibroblasts are known to play critical roles in lung maturation through stimulating alveolarization during the period of septation and in lipid homeostasis by mediating lipid transfer to type 2 alveolar epithelial cells for surfactant phospholipid synthesis. Furthermore, these mesenchymal cells have been demonstrated to have transient proliferative capacity,[43] which is similar to interstitial fibroblasts in animal models of lung development and injury.[44–46] Within these models, coordinated control of fibroblast proliferation and apoptosis is necessary for septation of the distal airspaces during alveolarization.[47] Collectively, this evidence including the presence of lipofibroblasts in PIG strongly suggests that aberrant lung development is a critical component of PIG.

## Clinical Features and Presentation

Most infants with PIG are symptomatic in the first days to weeks of life, which may follow an initial period of well-being after birth. The clinical presentation can be variable, ranging from indolent tachypnea and hypoxia to neonatal acute respiratory failure and pulmonary hypertension. The initial report of PIG included seven neonates, and five of whom presented in the first 24 hours of life.[40] In the ChILDRN study,[3] six cases (3.2% of infant lung biopsies) were identified in which PIG was the only significant histologic finding. All but one case presented with hypoxemia at birth, and the mean age at biopsy was 1.3 ± 0.4 months. There is clinical and pathologic evidence to support that PIG is often a self-limited disorder, and the diagnosis is typically made by 6 months of age.[3,40,43]

PIG can occur in either term or premature infants and may be an isolated disorder or a component of other congenital conditions. PIG commonly occurs in the setting of lung growth abnormalities (see earlier) and has also been observed in infants with congenital heart disease, Trisomy 21, pulmonary hypertension, meconium aspiration, and rarely other developmental anomalies.

## Radiologic Findings

Case series have reported that chest radiographs have diffuse infiltrates or hazy opacities, but no common high-resolution CT (HRCT) scan pattern has been identified (Fig. 56.4A–D).[3,48–51]

H

**FIG. 56.4** Imaging and histologic findings in pulmonary interstitial glycogenosis. Chest HRCT (A and B) from a

2-week old infant shows diffuse interstitial markings and interlobular septal thickening present bilaterally throughout all lung zones. This 38-week estimated gestational age infant had no respiratory difficulties at birth but required supplemental oxygen in the first days of life, intubation on day of life 5, and nitric oxide for severe pulmonary hypertension. Chest radiographic (C) and HRCT (D) images from a 5-month-old, former 34-week preterm infant show diffuse coarse interstitial and parenchymal abnormalities including architectural distortion and cystic change. This infant had persistent tachypnea and hypoxemia without need for mechanical ventilation; lung biopsy (E) (H&E, ×40) performed at 5 months of age showed patchy pulmonary interstitial glycogenosis *(asterisks)* and moderate deficient alveolarization, which is consistent with a lung growth abnormality. (F) On higher power (H&E, ×200), the bland spindled cells of pulmonary interstitial glycogenosis are seen to widen the alveolar septae *(arrows).* These cells contain glycogen (G) (periodic acid Schiff stain, ×200) and show strong immunoreactivity with vimentin (H) (×200).

## Histologic Findings

Formally known as cellular interstitial pneumonitis and histiocytoid pneumonia,[52] the term *PIG* was coined by Canakis et al. based on the histologic finding of increased glycogen-laden mesenchymal cells in the alveolar interstitium.[40] Lung biopsy shows a patchy or diffuse expansion of the alveolar walls by bland spindle-shaped cells with pale or bubbly cytoplasm (see Fig. 56.4E and F). Patchy distribution is frequent when there is a concomitant lung growth abnormality,[3] and associated inflammation or fibrosis in the interstitium is absent. The cells are strongly immunopositive for vimentin, a mesenchymal marker, and periodic acid–Schiff (PAS) stain may demonstrate PAS positive diastase labile material within the cytoplasm of the cells (see Fig. 56.4G and H). As the preservation of glycogen is influenced by using aqueous fixatives (i.e., 10% formalin), the presence of PAS positivity may be difficult to demonstrate on routine sections. Electron microscopy is considered the best approach to reveal the accumulation of monoparticulate glycogen in these interstitial cells, and treating ultrathin sections with tannic acid enhances visualization of glycogen.[40]

## Diagnosis and Differential Diagnosis

Currently, lung biopsy is the only way to diagnose PIG. The diagnosis may be suspected in the context of a neonate with respiratory compromise, particularly when the severity is disproportionate to the degree of coexisting conditions, including prematurity and congenital heart disease.

Disorders to be considered in the clinical differential diagnosis include sepsis, congenital heart disease, lung developmental disorders (e.g., alveolar capillary dysplasia with misalignment of the pulmonary veins), pulmonary hypoplasia, pulmonary vascular disease, lymphangiectasia, and genetic disorders of surfactant production and metabolism. Primary ciliary dyskinesia (PCD) could also mimic milder cases of PIG due to the frequent occurrence of neonatal tachypnea in PCD.[53] From the perspective of the pathologist, careful attention is required to identify potential concurrent histologic findings, such as lung growth abnormalities or structural alterations of the pulmonary vasculature.

## Management and Treatment

Most children will require supplemental oxygen and some will require aggressive support including mechanical ventilation and therapy for pulmonary hypertension. When present, comorbidities such as congenital heart disease or complications of prematurity are often the focus of management.

High-dose intravenous corticosteroids have been reported to have benefit in case reports and case series,[40,43,48,49] but no controlled studies have been performed and there is little evidence to guide therapeutic recommendations. It has been suggested that consideration for use of corticosteroids should be assessed in the context of clinical severity and the potential detrimental impact on postnatal alveolarization and neurodevelopment in this patient population.[51]

## Prognosis

The natural history is unknown, but mortality is largely related to complications of prematurity or pulmonary hypoplasia.[3,40,51] Patients may remain symptomatic for months, and supportive care is a mainstay of therapy. In the original report by Canakis et al., six of the seven infants improved over time, with mortality occurring in one infant born at 25 weeks gestation.[40] Similarly, in the ChILDRN study, no mortality occurred among the six cases of diffuse PIG,[3] and clinical improvement has also been reported in the small number of published case reports.[43,48,50] However, high mortality has occurred when significant pulmonary conditions are present along with PIG, particularly lung growth abnormalities.[43,51]

# Neuroendocrine Cell Hyperplasia of Infancy

## Epidemiology

NEHI is a rare disorder previously termed "Persistent Tachypnea of Infancy."[54,55] The incidence and prevalence of NEHI are unknown, and it is suspected that many cases remain undiagnosed, although cases are increasingly recognized worldwide.[56–61] In the ChILDRN study, NEHI cases represented 10% of all lung biopsies from children less than 2 years of age.[3] A recent study from a large referral center identified 19 cases (14%) from among 138 lung biopsy cases accrued over a 10-year period.[62] The original series of 15 cases had a slight male predominance, which was not observed in a subsequent study.[51,55]

## Etiology and Pathogenesis

The etiology of NEHI is unknown, but genetic mechanisms play a role in at least some cases.[63] In one family, a heterozygous mutation in *NKX2.1* (also called thyroid transcription factor 1, or TTF1) was identified in association with familial NEHI.[64] The mutation results in a nonconservative amino acid substitution in the homeodomain in a codon extensively conserved through evolution. To date, *NKX2.1* mutations have not been identified in other NEHI cases.

Lung biopsies in NEHI are characterized by prominent pulmonary neuroendocrine cells (PNECs) in the distal airways, but the role of PNECs in NEHI pathogenesis remains uncertain. A study correlating PNEC prominence and the severity of small airway obstruction on infant PFTs in NEHI patients suggests a potential causal role.[62] Based on the role of PNECs and bombesin in oxygen sensing as well as airway and arterial tone, it has been hypothesized that neuroendocrine cells may lead to ventilation/perfusion mismatch within the lung.[55] The physiologic abnormalities observed on infant pulmonary function tests in NEHI suggest that the disorder is not fully explained on this basis. The absence of active neuroendocrine cell proliferation in lung biopsies and lack of correlation with airway injury suggest that PNEC prominence in NEHI is not due to injurious stimuli.

## Clinical Features and Presentation

NEHI occurs in otherwise healthy-term or near-term infants who present with tachypnea and retractions, generally of insidious onset, in the first few months to year of life. Rare cases in preterm infants have been documented. Hypoxemia is common, while chronic cough and wheezing are rare.[55] Many patients come to medical attention because of failure to thrive or exacerbation of chronic symptoms with upper respiratory infections. However, respiratory symptoms are often mistakenly attributed to more common disorders such as bronchiolitis, gastroesophageal reflux, or aspiration.[56,60] On physical exam, crackles are prominent but variably present. Chest wall deformity with increased anteroposterior diameter is common, while clubbing has not been reported.

Infant pulmonary function testing (PFT) in NEHI patients demonstrates a mixed physiologic pattern including profound air-trapping and proportionate reductions in the forced expiratory volume in 0.5 seconds (FEV0.5) and forced vital capacity (FVC), with particularly reduced FEF75 and FEF85 and markedly elevated functional residual capacity (FRC), residual volume (RV), and RV/TLC. Pulmonary function testing has not been systematically studied in older children, although limited published data and personal experience suggest that this physiologic pattern can persist in at least some cases.[58,65,66]

## Radiologic Findings

Chest radiographs may be normal or may reveal hyperinflation.[55] HRCT findings are distinctive with geographic ground-glass opacities centrally and in the right middle lobe and lingula (Fig. 56.5A–C). Air-trapping is often demonstrated when expiratory images are performed. Brody et al. evaluated chest HRCT scans from 23 children with biopsy-proven NEHI and 6 children with other forms of ILD. While HRCT specificity for the diagnosis of NEHI was 100% in this study when the CTs were reviewed by two expert radiologists, the sensitivity of HRCT was incomplete, as readers did not suggest NEHI in up to 22% of the cases.[67]

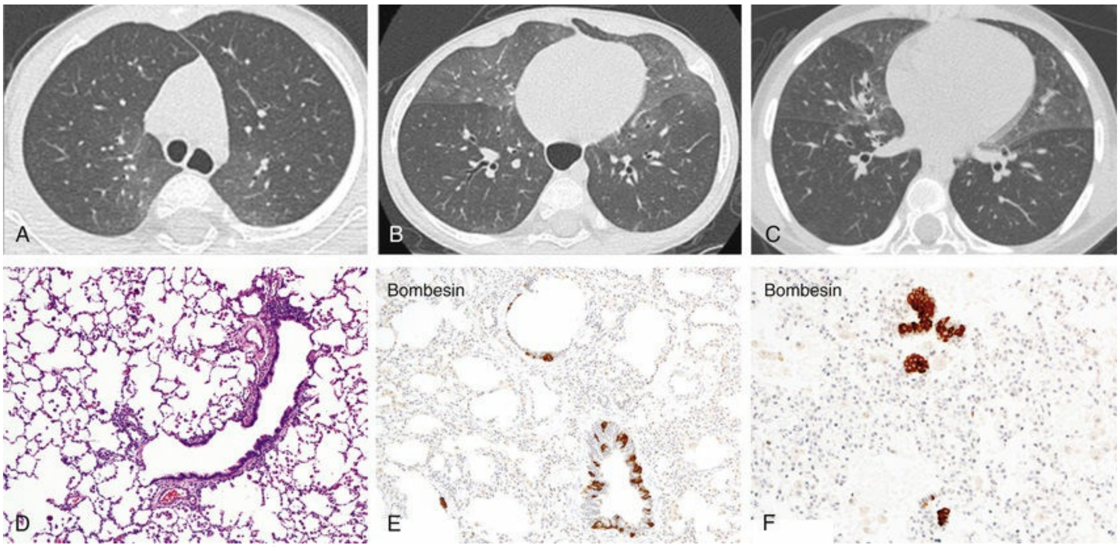

**FIG. 56.5** Characteristic radiographic and pathologic findings in neuroendocrine cell hyperplasia of infancy (NEHI). (A and B) A 13-month-old term infant presented at age 6 months with chronic tachypnea, retractions, and hypoxemia, had chronic indolent respiratory symptoms since the first month of life and poor weight gain since 5 months of age. HRCT images obtained at total lung capacity under general anesthesia show well defined regions of apparent ground glass opacity in the medial portions of the

upper lobes (A) and in the right middle lobe and lingula (B). Diffuse air-trapping was seen on expiratory images (not shown). (C) HRCT shows a similar pattern of apparent regional ground glass opacity in a 3-year-old with chronic tachypnea, retractions, and crackles since infancy being treated for recurrent pneumonia and refractory asthma. No additional radiographic abnormalities were identified. (D). Lung biopsies from NEHI patients typically show essentially normal histology. Mild nonspecific changes that may be present in the biopsy include mild periairway lymphocytic aggregates and increased alveolar macrophages (H&E, ×100). Increased neuroendocrine cells within bronchioles is best visualized by bombesin immunostaining (E) (×100). (F) Neuroepithelial bodies (NEBs) around alveolar ducts are frequently prominent (×200).

## Histologic Findings

In contrast to the clinical severity of the disorder, lung biopsies in NEHI often show minimal to no pathologic alterations and may be initially interpreted as normal (see Fig. 56.5D). Patchy mild inflammation or fibrosis (bronchiolitis) may be present, especially following a viral infection, but this not sufficient to support an etiology for the patient's significant symptomatology. Pathologic diagnosis of NEHI rests on finding an increased proportion of neuroendocrine cells within distal airways, best seen by bombesin and serotonin immunohistochemistry.[55,59,61] Neuron-specific enolase, calcitonin, synaptophysin, and chromogranin have been shown to be less reliable in demonstrating this increase in neuroendocrine cell numbers. Immunohistochemical assessment of this disorder requires an adequate biopsy with at least 10–15 airways for evaluation. As wide intra and intersubject variability in neuroendocrine cell number has been reported, which does not relate to imaging appearance of the region biopsied, more than one biopsy site is recommended. Morphometric quantification of bombesin staining may be required. In general, bombesin immunopositive cells in NEHI are prominent in the distal respiratory bronchioles and as clusters (neuroepithelial bodies) in the alveolar ducts (see Fig. 56.5E and F). Two individual airways with more than 10% bombesin-immunopositive area or cell number of the airway epithelium is also suggestive of the diagnosis, although may not be present.[59] A minor degree of airway injury does not alter pathologic confirmation of the diagnosis.

## Diagnosis and Differential Diagnosis

Clinical suspicion is essential in the diagnosis of NEHI. The initial diagnostic approach should be to exclude more common causes of the clinical symptoms such as infection, cystic fibrosis, and congenital heart disease. In the appropriate clinical context, the diagnosis may be made by chest HRCT in a majority of cases and sometimes be supported by data from infant PFTs, which may play a role in supporting the diagnosis of NEHI.[68] At this time, genetic testing is not routinely helpful in making the diagnosis.[64]

Although lung biopsy is the historical gold standard, lung biopsy is not required to make the diagnosis except in patients with atypical clinical or HRCT findings. There are important limitations to lung biopsy. Specifically, the numbers of PNECs are variable and not always seen without sufficient airway sampling. Furthermore, the presence of increased number of neuroendocrine cells on lung biopsy is not sufficient for the diagnosis, as PNEC prominence is associated with a variety of other pulmonary conditions, including BPD, sudden infant death syndrome, pulmonary hypertension, cystic fibrosis, and follicular bronchiolitis.[59,69–74]

Disorders to be considered in the clinical differential include acute or chronic infection, asthma, and airway injury including bronchiolitis obliterans. In addition, other infant lung disorders such as pulmonary hypoplasia, PIG and genetic disorders of surfactant production, and metabolism should be considered. As discussed previously, neuroendocrine cell prominence on lung biopsy should be correlated with other potential pathologic findings, and other entities associated with increased neuroendocrine cells excluded.

## Management and Treatment

There is no known definitive therapy for NEHI, and management largely consists of general supportive and preventative care. Most children will require supplemental oxygen, and many will require nutritional supplementation. Corticosteroids are not helpful in most cases[55]; therefore establishment of the diagnosis of NEHI helps to avoid the complications of long-term steroid therapy. Genetic counseling and family support are important components of care for all families who experience the diagnosis of a rare disease.

## Prognosis

While long-term outcomes are not well established for this recently recognized disorder, a diagnosis of NEHI brings a cautious but welcomed prognosis relative to other forms of childhood ILD. There have been no deaths reported, and no patients have required lung transplantation.[3,55] The clinical course is prolonged, but most children demonstrate gradual improvement. The need for supplemental oxygen is variable and may be many years in duration.[55,58] Patients may also remain symptomatic with respiratory infections or exercise intolerance.[63,75] In one report, six of nine infants developed a phenotype consistent with nonatopic asthma.[58] Exacerbations, with concomitant air-trapping, have also been described.[65] The CT abnormalities may persist into adulthood in at least some cases, but the time course of radiologic resolution in relationship to clinical parameters has not been systematically studied.[64,66]

# Summary

Despite overlapping clinical features most forms of ILD have distinct imaging and histologic findings (Table 56.2). Recognition of these disorders informs diagnostic approach, enables timely diagnosis, and has implications for management and prognosis.

### Table 56.2

**Forms of Childhood Interstitial Lung Diseases “More Prevalent in Infancy”**

| | Alveolar Capillary | Neuroendocrine | Pulmonary |
|---|---|---|---|

| **Disorder**[a] | **Dysplasia With Misalignment of the Pulmonary Veins** | **Lung Growth Abnormalities** | **Cell Hyperplasia of Infancy** | **Interstitial Glycogenosis** |
|---|---|---|---|---|
| Common age of presentation | Birth | Birth | Infancy with most in first year of life<br>Rare at birth | Early neonatal |
| Hereditary basis | Yes<br>*FOXF1;* autosomal dominant | Uncertain<br>Frequent in association with chromosomal abnormalities | Suspected<br>Not established | Unknown |
| Associated features | Other congenital anomalies<br>PHTN | Prematurity<br>Congenital heart disease<br>Trisomy 21<br>PHTN | None known | Prematurity<br>Congenital heart disease<br>PHTN |
| Common Imaging Pattern | Uncertain | Variable<br>May include architectural distortion, cystic change | CXR: Hyperinflation, normal, or mild perihilar infiltrates<br>HRCT: GGO in RML and lingual Air-trapping | Variable<br>Frequent diffuse interstitial infiltrates |
| Diagnostic approach | Lung biopsy; emergence of genetic testing | Clinical context, lung biopsy | Lung biopsy definitive<br>HRCT and iPFTs may strongly suggest | Lung biopsy |
| Outcome | Fatal without lung transplant[b] | Variable | Gradual improvement (years) | Variable |

[a] Genetic disorders of surfactant production and metabolism are also more prevalent in infants and young children. See Chapter 57.

[b] Variable penetrance and phenotype data emerging.

*FOXF1*, Forkhead Box F1 gene; *GGO*, ground-glass opacities; *iPFT*, infant pulmonary function test; *PHTN*, pulmonary hypertension; *RML*, right middle lobe.

## 57

# Lung Diseases Associated With Disruption of Pulmonary Surfactant Homeostasis

*Lawrence M. Nogee MD, Bruce C. Trapnell MD*

Pulmonary surfactant is a mixture of specific lipids and proteins that reduces surface tension at the air-liquid-tissue interface, thereby preventing alveolar collapse at end expiration. This critical function requires tight regulation of alveolar surfactant composition and quantity (i.e., surfactant homeostasis), which is achieved through coordinated expression of multiple genes resulting in balanced production and clearance of surfactant.

The most common lung disorder associated with disruption of surfactant homeostasis is the respiratory distress syndrome (RDS), which occurs mainly in premature infants, principally due to surfactant deficiency from insufficient production by alveolar epithelial cells secondary to immaturity. Another disorder of surfactant homeostasis is pulmonary alveolar proteinosis (PAP), a syndrome (not a disease) characterized by the slow, progressive accumulation of surfactant lipids and proteins within alveoli resulting in displacement of air and impairment of oxygen uptake. The most common cause of the PAP syndrome is an autoimmune disease mediated by neutralizing autoantibodies against the cytokine granulocyte-macrophage colony-stimulating factor (GM-CSF). High levels of GM-CSF autoantibodies block GM-CSF stimulation of alveolar macrophages, which is critical for enabling surfactant clearance by these cells. Although autoimmune PAP occurs most commonly in adults and adolescents, it has been seen in children as young as 3 years old.

Single-gene mutations that disrupt the production of normal surfactant and that impair GM-CSF–dependent surfactant clearance by alveolar macrophages have been identified. These genetic disorders of surfactant homeostasis can be usefully categorized as disorders of surfactant production or surfactant clearance. The clinical presentation and features, pathogenesis, natural history, therapeutic responses, and prognosis of individual disorders of surfactant homeostasis vary widely. Although rare, these disorders are associated with significant morbidity and mortality. A heightened awareness can improve early recognition, accurate diagnosis, and facilitate counseling about prognosis and the risk of disease recurrence in future pregnancies. Understanding the pathophysiology of these disorders provides potential insights into normal surfactant metabolism and how genetic mechanisms contribute to more common diseases, such as neonatal RDS.

This chapter summarizes current knowledge concerning disorders of surfactant production and clearance that cause acute and chronic lung disease. Further advances in the understanding of lung development and surfactant metabolism combined with technological advances and data derived from the human genome project are likely to allow for continued identification of novel genetic mechanisms for neonatal and pediatric lung disease.

# Epidemiology

## Overview of Surfactant Composition and

# Metabolism

Pulmonary surfactant is a complex mixture of phospholipids, neutral lipids, and specific proteins that is produced by the alveolar type II epithelial cell (AEC2), stored in intracellular organelles known as lamellar bodies, and secreted by exocytosis into the alveolar lumen. The major lipid present in pulmonary surfactant is phosphatidylcholine (PC), a large fraction of which contains two palmitic acid side chains that are fully saturated (dipalmitoyl or disaturated phosphatidylcholine, DPPC or DSPC); its presence is critical for surfactant to function in reducing surface tension. ABCA3 is a member of the adenosine triphosphate (ATP) binding cassette family of membrane transporters that is located on the limiting membrane of lamellar bodies and has a key role in the transport of phospholipids into lamellar bodies during the biosynthesis of surfactant. The effective lowering of surface tension also requires the presence of one or both of two extremely hydrophobic surfactant proteins (SPs), SP-B and SP-C. Pulmonary surfactant also contains two larger glycoproteins, SP-A and SP-D, which are members of the collectin family, having both a collagenous domain and a carbohydrate-binding domain. The principal roles for SP-A and SP-D appear to be in local host defense and immunomodulation rather than surface tension lowering.[1,2] The production of ABCA3 and SP-A, SP-B, SP-C, and SP-D is developmentally regulated and increases during gestation. Specific transcription factors that bind to DNA sequences in the promoter regions of each gene are important for the proper expression of each protein, including thyroid transcription factor 1 (TTF-1), which is encoded by the gene *NKX2-1*.[3,4] Mutations in the genes encoding SP-A *(SFTPA1, SFTPA2)* have been associated with the phenotypes of pulmonary fibrosis and lung cancer in adults; disease-causing mutations in the gene encoding SP-D *(SFTPD)* have not yet been reported.[5–7]

After secretion, pulmonary surfactant is both recycled into AEC2s and is cleared by alveolar macrophages. For macrophages to properly mature and efficiently catabolize surfactant, GM-CSF must bind to a specific receptor at the cell surface and initiate specific signaling events. The receptor is composed of two chains: a specific ligand-binding α chain (CD116) and a β chain (CD131) that enhances affinity and is shared with the receptors for interleukin (IL)-3 and IL-5.[8,9] Binding of GM-CSF to its receptor initiates intracellular signaling cascades and activates the transcription factor PU.1, which regulates multiple alveolar macrophage functions, including the ability to catabolize surfactant components (Fig. 57.1).[10]

**FIG. 57.1** Simplified overview of surfactant production and clearance. Surfactant lipids and proteins are synthesized by alveolar type II cells, with thyroid transcription factor 1 *(TTF-1)* needed for transcription of SP-B, SP-C, and ABCA3. SP-B and SP-C are synthesized as proproteins and processed in lamellar bodies. The lamellar bodies fuse with the apical cell membrane, and the surfactant complex is secreted by exocytosis, with SP-B and SP-C helping enhance adsorption to the air-liquid interface and organize surfactant lipids. Surfactant material is recycled through type II cells by endocytosis and taken up in multivesicular bodies. Surfactant is internalized and its components broken down in the phagolysosomes of

alveolar macrophages. Binding of granulocyte-macrophage colony-stimulating factor *(GM-CSF)* to its receptor initiates signaling pathways leading to nuclear binding of the transcription factor PU.1 to regulatory elements in genes needed for macrophage maturation and functions, including clearance of surfactant.

## Epidemiology of Surfactant Production Disorders

The precise incidence and prevalence of disorders of surfactant production and clearance are unknown, although both relative and absolute estimates may be made based upon case ascertainment and population-based studies of the frequency of deleterious genetic variants identified in each of the responsible genes *(SFTPB, ABCA3, SFTPC, NKX2-1, CSF2RA, CSF2RB)*. Publicly available databases of genetic variants identified through large-scale exome sequencing of different populations are available, including the 1000 genomes project (www.1000genomes.org), Exome Aggregation Consortium (exac.broadinstitute.org), and Exome Sequencing Project of the US National Institutes of Health (evs.gs.washington.edu/EVS/). However, the potential clinical significance of most of the variants listed is usually unclear, and thus caution is needed in the interpretation of findings from these databases in inferring the population frequency of potentially deleterious variants.

Hereditary SP-B deficiency was the first recognized genetic abnormality of surfactant production but is probably the rarest.[11] Fewer than 60 cases have been reported in the literature.[12] The carrier frequency of the most commonly encountered mutation in the SP-B gene *(SFTPB)* in the US population was estimated to be approximately 1 in 1000 individuals.[13,14] Combining this finding with the observation that this mutation has accounted for approximately ⅔ of the mutant *SFTPB* alleles identified to date, this would predict a disease incidence of 1 in 1.5 million live births. The relative incidence in other countries and subpopulations may differ: the carrier rate for the same mutation in Denmark was found to be 1 in 560 individuals, which would still predict a very low incidence of disease.[15] This mutation has been found mainly in individuals of Northern European descent, and the incidence of deleterious *SFTPB* mutations in other populations may be even less. SP-B deficiency has not been recognized in Japan, and the prevalence of likely pathogenic mutations in databases obtained from large-scale exome sequencing studies is very low.[16,17]

More than 250 subjects with ABCA3 deficiency have been reported, and the relative frequency with which ABCA3-deficient infants have been identified compared with those with other genetic surfactant disorders suggests that it may be the most frequent cause of genetic surfactant dysfunction.[18–23] This would not be surprising given the relatively large size of *ABCA3.* The predicted incidence of ABCA3 deficiency disease ranged from 1 in 3500 to 1 in 20,000 live births in a study that used estimates of the population frequency of possible disease-causing mutations.[24] These estimates seem high given available data on the incidence of neonatal respiratory failure in term infants and childhood interstitial lung disease (ILD).[25–27] Some of the DNA sequence variants considered disease causing may be benign, or there may be patients with milder or variant phenotypes who are not recognized.

The incidence and prevalence of lung disease associated with *SFTPC* mutations are unknown. Approximately 170 subjects have been reported to date, although some subjects are represented in more than one report.[22,28–32] The population frequency of the most frequently encountered mutation, called p.Ile73Thr (or p.I73T), was examined in samples obtained from neonatal screening programs but was not found on any of almost 9000 alleles examined, precluding a reliable estimate.[14] The ExAc database lists three *SFTPC* alleles that have been reported as disease causing (p.I73T, p.V102M, p.A112T) out of approximately 120,000 sequenced, implying a minimal disease-estimate of 1 in 40,000, although clinical data on these subjects are not available.

The incidence of lung disease due to *NKX2-1* mutations or deletions is unknown. Almost 200 patients with deleterious *NKX2-1* genetic variants have been reported, but such variants may also cause neurologic symptoms or hypothyroidism in the absence of lung disease, and in approximately ⅓ of reported cases either a pulmonary phenotype was not recognized or formally investigated.[33–41] Such mutations appear to be a rare cause of congenital hypothyroidism,[42,43] but studies focusing on the frequency of the pulmonary phenotype have not been performed. None of the sequence variants listed in the ExAc database have been reported as disease causing, precluding an estimate of disease incidence using this resource.

## Epidemiology of Surfactant Clearance Disorders

Autoimmune PAP accounts for approximately 85% of all PAP cases, with an incidence and prevalence, respectively, of 0.42 and 6–7 per million in the general population.[44,45] The disorder affects all races and ethnic groups, is globally distributed, and is more common in men than women, due to the increased frequency of smoking among men. The disease usually presents in the third to fifth decade of life, with progressive dyspnea of insidious onset and diffuse bilateral lung infiltrates on radiologic evaluation. The presentation is similar in younger adults, adolescents, and children as young as 3 years of age. Clubbing is not a feature, although occasionally fever and hemoptysis may be present and usually indicate the presence of a secondary infection.

Approximately 35 people with hereditary PAP due to mutations in *CSF2RA* or *CSF2RB* have been reported to date, and population estimates of the frequency of these disorders are not available.[46–52]

# Etiology

## Disorders of Surfactant Production

ABCA3 is a 1704–amino acid protein with two membrane-spanning and two nucleotide-binding domains encoded by single gene *(ABCA3)* spans on human chromosome 16. ABCA3 expression increases with advancing gestation, and its expression can be pharmacologically increased by glucocorticoids.[53–55] ABCA3 is also expressed at low levels in several other tissues, including kidney, intestine, thyroid, and brain.[53–56] ABCA3 deficiency is inherited in an autosomal recessive fashion, with disease resulting from loss-of-function mutations on both *ABCA3* alleles. Genetically engineered mice lacking ABCA3 do not inflate their lungs and die from respiratory failure perinatally, supporting that disruption of ABCA3 gene function is the cause of the findings in children with biallelic ABCA3 mutations.[57–60]

SP-B is a 79–amino acid protein encoded on a single gene *(SFTPB)* on human chromosome 2. The gene is now thought to contain 12 exons, the last of which is untranslated, and directs the production of a 393–amino acid primary translation product. This SP-B preproprotein was previously believed to be 12 amino acids smaller, but the translational initiation site is now thought to be 36 bases further upstream, although direct experimental data are lacking. The proprotein undergoes proteolytic processing to yield the mature, very hydrophobic protein found in the airspaces, which is encoded in exons 7 and 8.[61,62] SP-B is produced primarily by AEC2s, routed to lamellar bodies, and secreted along with surfactant phospholipids into the airspaces. The gene is also expressed within the lung in nonciliated bronchiolar epithelial cells, although only AEC2s fully process the proprotein (proSP-B) to mature SP-B.

SP-B deficiency is inherited as an autosomal recessive disorder due to loss-of-function mutations on both alleles. The first recognized *SFTPB* mutation remains the most frequently identified and involves a net 2-base insertion in what, at the time of its discovery, was thought to be codon 121, and the mutation was thus termed 121ins2.[63] The mutation results in a frameshift and premature codon for the termination of translation; current terminology for this variant is c.397delCinsGAA (p.P133Q*fs**95), and a common ancestral origin likely accounts for it being found in multiple unrelated individuals.[64] More than two dozen other SP-B mutations have been identified, as well as a deletion spanning exons 7 and 8.[12,21,65–71] Most of these mutations are unique to a given family, although several mutations have been identified in apparently unrelated families in certain ethnic groups.[65]

SP-C is an extremely hydrophobic 35–amino acid protein encoded by a single gene *(SFTPC)* on human chromosome 8, containing 6 exons, of which the sixth is untranslated. Mature SP-C, encoded in the second exon, is derived from proteolytic processing of a larger precursor protein (proSP-C) of 191 or 197 amino acids, depending upon alternative splicing at the beginning of exon 5. The last 100 amino acids of proSP-C have homology with a group of proteins known as BRICHOS that are mutated in some familial dementias.[72] Proper folding of this domain may provide an important chaperone function in terms of moving the hydrophobic proSP-C protein through the cell.[73,74]

Lung disease resulting from mutations in *SFTPC* is either inherited in an autosomal dominant fashion with variable penetrance, or sporadic disease may occur due to de novo mutations.[28–31,75–86] A mutation on one allele is sufficient to cause disease, although subjects with biallelic mutations have been reported.[16,29,32,77,87–89] One mutation, a predicted substitution of isoleucine for threonine in codon 73 (p.Ilet73Thr or p.I73T), has accounted for 35%–50% of the mutant *SFTPC* alleles reported to date from multiple unrelated families.[28,75–77,86,90–92] This mutation has arisen on genetically diverse *SFTPC* alleles, suggesting recurrent mutation as the mechanism for a common mutation.[77,86] Most other reported mutations are in the region encoding the BRICHOS domain.

TTF-1 is a member of the homeodomain-containing family of transcription factors encoded by a single, three exon gene *(NKX2-1)* on human chromosome 14q13.3.[3,93] *NKX2-1* is also expressed in the thyroid, where it is important for development of that gland, and in the central nervous system (CNS) (primarily basal ganglia). In the lung, it is critical for the expression of ABCA3, SP-A, SP-B, and SP-C, along with many other genes.[54,93,94]

Familial lung disease inherited in an autosomal dominant pattern with variable penetrance due to *NKX2-1* mutations and deletions has been recognized, but most reported cases appear to have resulted from de novo events.[34,36,38,40] Unlike disorders due to mutations in *ABCA3, SFTPB,* or *SFTPC,* patients with *NKX2.1* mutations or deletions may have extrapulmonary manifestations of hypothyroidism and neurologic findings, and the term “brain-thyroid-lung syndrome” has been used to encompass the constellation of findings.[34,95–97] Approximately 50% of reported patients with *NKX2.1* deletions or mutations had some pulmonary disease, but detailed evaluation of lung function was not necessarily performed in all subjects.[34] Affected individuals need not have abnormalities in all three organ systems and may have normal thyroid function, or chemical hypothyroidism may be present without clinical symptoms. The neurologic findings may be subtle in infants, consisting of nonspecific hypotonia or developmental delay, and attributed to the severity of the lung disease. The more specific finding of chorea may not manifest until later in life.

## Disorders of Surfactant Clearance

A plethora of different terms have been used to report on PAP, resulting in inconsistent use of overlapping terminology; some brief definitions are useful here. Elucidation of the pathogenic mechanism of the most common PAP-associated disease (idiopathic PAP) was the basis for recommending use of the term "autoimmune PAP."[98] Genetic diseases causing hereditary PAP can be specified by the affected gene (i.e., *CSF2RA* or *CSF2RB*) encoding the GM-CSF receptor α- or β-chains, respectively. These autoimmune and genetic diseases share strikingly similar features, including clinical presentation (although age of presentation may be different), radiographic appearance, histopathology (alveolar filling without marked distortion), pathophysiology, overlapping pathogenesis (loss of GM-CSF signaling), and response to whole lung lavage therapy. Consequently, they are usefully considered together and sometimes called primary PAP, reflecting their occurrence in previously healthy individuals.

PAP occurring because of another underlying disease is referred to as secondary PAP. Diseases associated with the development of secondary PAP include hematologic disorders (e.g., myelodysplasia, hematologic malignancies, aplastic anemia), certain chronic infections (e.g., human immunodeficiency virus [HIV]), toxic inhalation exposures (e.g., silica fibers, metal dusts), and generalized myelosuppression caused by chemotherapy and hematopoietic stem cell transplantation. PAP may be a prominent finding in other genetic diseases not involving disruption of GM-CSF signaling (lysinuric protein intolerance [LPI], mutations in the gene encoding methionyl tRNA synthetase).[45,99–102]

PAP can also occur in disorders of surfactant production, as described previously. Pulmonary surfactant in these disorders is deficient in one or more of its critical components, resulting in deficiency of functional surfactant that causes marked alveolar distortion, a spectrum of acute and chronic ILDs, and varying degrees of accumulation of abnormal surfactant (PAP). The clinical presentation, response to whole lung lavage (which is poor), and therapeutic approaches are quite different from primary PAP in which the primary abnormality is the accumulation of biochemically and functionally normal surfactant without alveolar distortion.

## Autoimmune Pulmonary Alveolar Proteinosis

This disease is caused by an immune reaction to GM-CSF that blocks signaling to alveolar macrophages (and other cells), thereby impairing their ability to clear surfactant lipids and proteins. Neutralizing, polyclonal immunoglobulin (Ig)G (primarily IgG1 and IgG2) is associated with the development of PAP when levels exceed a critical threshold required to eliminate GM-CSF signaling in vivo (estimated to be approximately 5 μg/mL). Disruption of GM-CSF signaling blocks the differentiation of alveolar macrophages, impairing surfactant clearance and host defense functions. Loss of GM-CSF signaling also impairs neutrophil host defense functions, which, together with impairment of macrophage host defense functions due to maturational arrest, provide a molecular and cellular explanation for the increased morbidity and mortality from infection seen in this disorder.[103] Impaired pulmonary surfactant clearance caused by alveolar macrophage dysfunction results in a slow net accumulation of surfactant within alveoli, which blocks the entry of air and transfer of oxygen into the blood, eventually resulting in hypoxemia and respiratory insufficiency. Alveolar distortion is not a prominent histopathologic feature in most patients, but lymphocytosis can be present and fibrosis has also been reported.

## Pulmonary Alveolar Proteinosis Caused by Autosomal Recessive *CSF2RA* Mutations

In 2008 two groups independently reported children with the phenotype of PAP who had deleterious variants in the gene encoding the $\alpha$-chain of the GM-CSF receptor *(CSF2RA)*, which is located within the pseudoautosomal regions of the X and Y chromosomes. In one report, two sisters were found to be compound heterozygotes for a complete deletion of the *CSF2RA* locus and a missense mutation that was demonstrated in vitro to produce nonfunctional GM-CSF receptors.[49] The proband developed progressive dyspnea apparent by age 4, was diagnosed with PAP on lung biopsy at age 6, and responded well to whole lung lavage therapy. Her 8-year-old sister had the same genotype and evidence for mild PAP by high-resolution computed tomography (HRCT) but was asymptomatic at the time of the report and had not needed any therapy for PAP. These two genetically similar siblings illustrate the phenotypic variability of this disorder. In another report a child with Turner syndrome (45 XO) was diagnosed with PAP at age 3 years, confirmed on biopsy, and found to have a partial deletion of *CSF2RA* accounting for the lack of receptor expression and GM-CSF signaling.[104] The child died of a respiratory infection following a bone-marrow transplant prior to engraftment.

A subsequent study expanded on these initial observations with the identification of five additional patients with deleterious *CSF2RA* genetic variants from three families of differing ethnicity and geographic origin, indicating that this disorder is not confined to one ethnic group or geographic location.[46] The age of onset of symptoms ranged from 1.5 to 9 years; one patient was asymptomatic. Usual presenting symptoms included dyspnea and fatigue. None of the subjects had autoantibodies to GM-CSF, but all had elevated serum levels of GM-CSF compared with family members and healthy control subjects. A variety of *CSF2RA* genetic defects were identified; CSF2RA protein was absent in all but one patient with a missense mutation, but all affected patients had reduced signaling induced by GM-CSF in isolated mononuclear cells. Symptomatic patients had undergone multiple whole lung lavages with intervals ranging from every several months to more than 2 years. All were alive at the time of the report, ranging in age from 4 to 13 years.[46]

## Pulmonary Alveolar Proteinosis Caused by Autosomal Recessive *CSF2RB* Mutations

A genetic defect of the GM-CSF receptor was first suggested as a mechanism for PAP in four infants who had undetectable amounts of the common β-chain (βc) shared with IL-3 and IL-5 receptors, as determined by immunologic methods.[105] Deficient response to exogenous stimulation by GM-CSF was also observed in monocytes obtained from affected infants. However, no convincing genetic mechanism was identified to account for the lack of βc, and the only genetic variant identified in its gene *(CSF2RB)* was subsequently found to be a nondisease causing polymorphism.[51]

Function-altering mutations in *CSF2RB* have since been reported in two unrelated patients.[51,52] Both presented with the typical symptoms and signs of PAP, one at age 9 and the other at age 36. Both had elevated levels of serum GM-CSF, and antibodies to GM-CSF were not detected. One patient was homozygous for a missense mutation that was confirmed in in vitro studies to be nonfunctional; the other was homozygous for a single base deletion in exon 6 and had no detectable βc protein. In contrast to the earlier report involving infants with absent βc protein expression, these reports provided convincing evidence that genetic defects in *CSF2RB* can cause the phenotype of PAP. The mechanism(s) for decreased βc expression in the infants in the earlier study and whether it contributed to the pathophysiology of their lung disease remain unknown. It is interesting that the age at presentation of patients with *CSF2RB* mutations was older than those with *CSF2RA* genetic variants, but additional patients will need to be identified to determine if there is a true difference in age of onset of disease depending upon the gene involved.

### Pulmonary Alveolar Proteinosis Syndrome Associated With Other Genetic Disorders.

Genetically determined primary defects in GM-CSF production have not been reported as a cause of PAP in humans, although this mechanism is expected based upon observations in experimental animals.[106,107] PAP develops in some but not all children with LPI, a disorder of cationic amino acid transport caused by mutations in the gene *SLC7A7*, a member of the solute carrier family.[100,108,109] The mechanism of PAP in children with LPI is unknown but appears likely to involve macrophage dysfunction rather than surfactant production, because defects are present in mononuclear phagocyte lineage cells.[110] PAP also recurred in a child with LPI who had undergone heart-lung transplantation, consistent with alveolar macrophages and not alveolar epithelial cells comprising the site of pathogenic disruption of surfactant homeostasis.[111]

Biallelic mutations in the gene encoding methionyl tRNA synthetase *(MARS)* have been identified in subjects with a complex multiorgan phenotype in which PAP can be the presenting and/or predominant feature.[99] Liver disease and anemia are common in affected subjects, and ILD was also observed in a child with this condition.[112] The mechanism whereby mutations in this gene result in the phenotype of PAP is unclear. As supplementation with additional methionine augmented function of enzymes in yeast that were homologous to human mutations, difference in dietary methionine intake may influence the severity and course of disease.

Heterozygous mutations in the gene encoding GATA2, a transcription factor important in hematopoietic cell development, have also been associated with the development of PAP. These subjects have a complex phenotype with features of immune deficiency, myelodysplasia, and lymphatic abnormalities, but PAP and diffuse lung disease may be prominent and presenting features.[113,114] The mechanisms underlying PAP are likely related to a role of GATA2 in regulating alveolar macrophage development and phagocytosis.[115]

# Pathology/Pathogenesis

## Disorders of Surfactant Production

The lung histopathology findings associated with genetic surfactant production disorders include several characteristic features and collectively have been referred to as surfactant dysfunction. Typical findings include marked AEC2 hyperplasia, interstitial thickening with mesenchymal cells progressing to fibrosis in subjects with late disease, and variable amounts of proteinaceous material and foamy macrophages in distal airspaces (Fig. 57.2). The proteinaceous material may be quite striking, particularly in younger patients, which led to the term congenital alveolar proteinosis initially being associated with SP-B deficiency.[11] However, findings of alveolar proteinosis are not always observed in SP-B deficiency and are also seen in other disorders of surfactant production and surfactant clearance, in which the underlying mechanisms differ. Thus the term congenital alveolar proteinosis is best avoided.

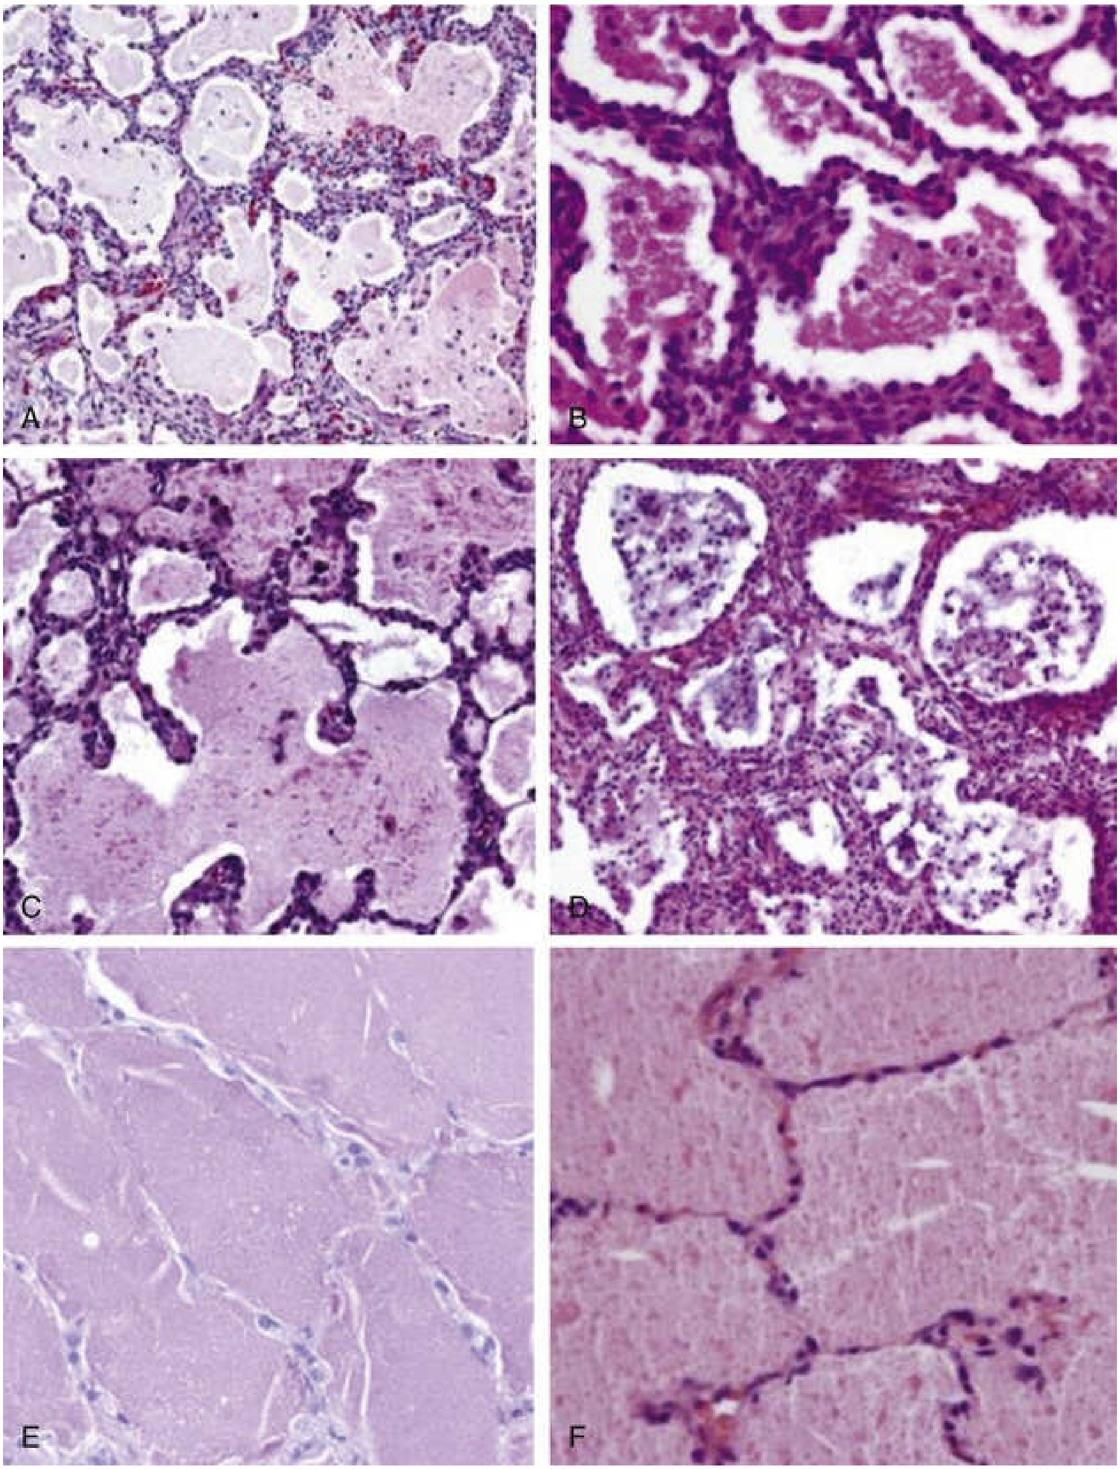

**FIG. 57.2** Variable and overlapping histology associated with genetic disorders disrupting surfactant homeostasis. (A) is from an SP-B–deficient infant, demonstrating marked accumulation of granular proteinaceous material with entrapped macrophages filling distal airspaces. (B) Similar pathology is demonstrated in a patient with ABCA3 deficiency and from a patient with an SP-C mutation (C), although with better preservation of the alveolar architecture in

C. (D) is from a patient with a different SP-C mutation, demonstrating interstitial thickening and accumulation of foamy macrophages in the airspaces, but with scant amounts of proteinaceous material. (E) and (F) are from patients with *CSF2RA* and *CSF2RB* mutations, respectively. Although the airspaces are totally filled with granular material, the alveolar walls remain thin without thickening by mesenchymal or inflammatory cells or fibrosis. ([A–F] Courtesy Susan Wert, PhD.)

The histopathology findings in different genetic lung disorders overlap considerably such that determination of the specific gene defect is not readily discernable from the routine histopathology. Pathology terms that have been used to describe the findings include chronic pneumonitis of infancy (CPI), desquamative interstitial pneumonia (DIP), and nonspecific interstitial pneumonitis (NSIP).[38,78,116,117] Lung pathology findings in children with *NKX2-1* mutations may include those observed with other causes of surfactant dysfunction, as well as alveolar simplification.[97,118,119]

Characteristic ultrastructural features may be seen in lung tissue from SP-B– and ABCA3-deficient infants by electron microscopy (Fig. 57.3).[20,120–125] The lamellar bodies in SP-B–deficient infants (and mice) are poorly organized, with loosely packed lamellae and vacuolar inclusions, having the appearance more of multivesicular or composite bodies. In contrast, absent or small, abnormally formed lamellar bodies have been observed in the lungs of ABCA3-deficient infants.[20,121,123,124,126] Their AEC2s instead contain small, dense-appearing inclusions that upon higher magnification have densely packed membranes. Eccentrically placed electron-dense inclusions within the abnormal lamellar bodies give them a “fried-egg” appearance.[123] Similarly, abnormal lamellar bodies have been observed in genetically engineered ABCA3 null mice.[58,60]

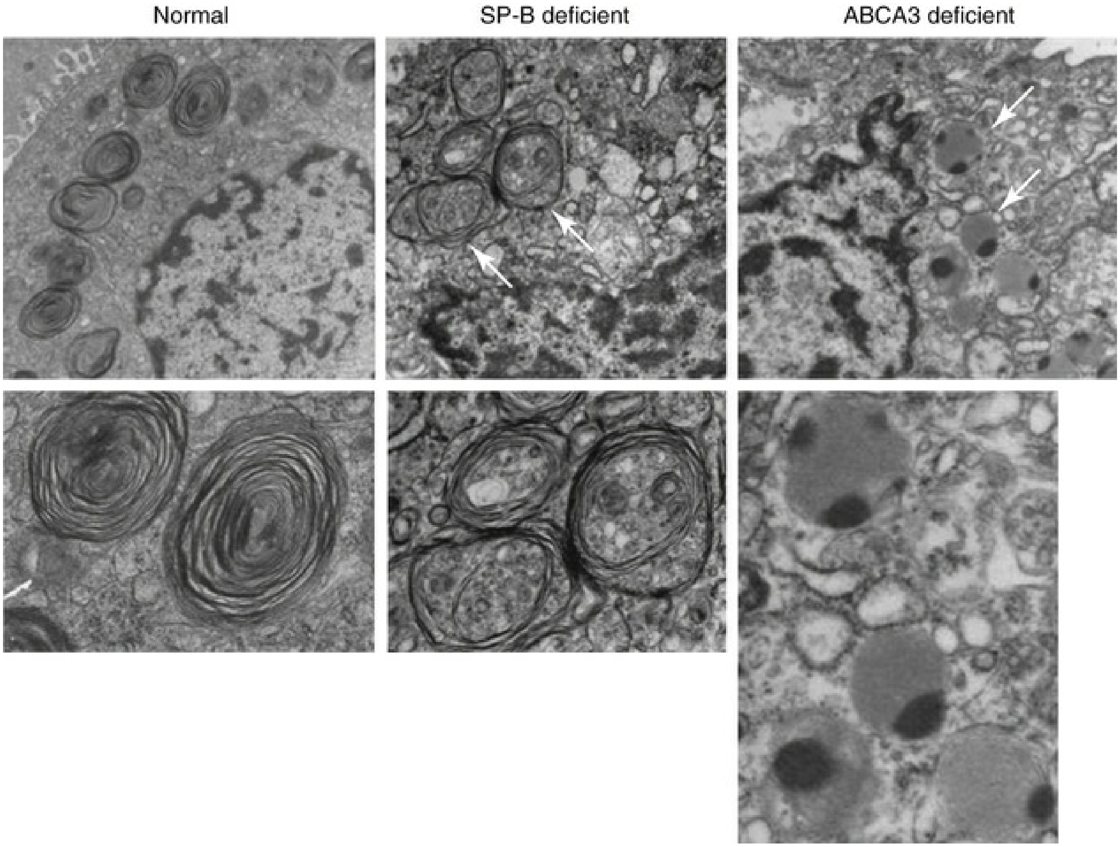

**FIG. 57.3** Ultrastructural findings associated with SP-B and ABCA3 deficiency. A portion of a type II cell with normal lamellar bodies is shown in the top left panel. In the top middle panel a type II cell from an SP-B–deficient patient contains abnormally formed lamellar bodies with large whorls and vacuolar inclusions *(arrows).* In the top right panel the lamellar bodies in the type II cells of a patient with ABCA3 deficiency are small and dense, with eccentrically placed inclusions *(arrows).* The bottom panels show higher-power views of normal *(left),* SP-B–deficient *(middle),* and ABCA3-deficient *(right)* lamellar bodies. (Courtesy Susan Wert, PhD.)

Specific ultrastructural features associated with *SFTPC* or *NKX2-1* mutations have not been consistently observed. Abnormally formed lamellar bodies have been observed in lung tissue from some children with *SFTPC* mutations[79,125] but have been reported as normal in other studies.[127] Abnormal lamellar bodies like those seen in SP-B–deficient or ABCA3-deficient infants have been observed in lung tissue from children with *NKX2-1* mutations, but a consistent pattern has not emerged.[38] Because TTF-1 is a transcription factor important for expression of both SP-B and ABCA3, the lamellar body phenotype may depend upon the impact of the specific mutation on relative expression of these target genes.

Both human and animal studies support that loss-of-function mechanisms resulting in both deficiency of surfactant components and altered surfactant composition and function are clearly important in the pathophysiology of the acute RDS phenotype observed in SP-B– and ABCA3-deficient infants. Bronchoalveolar lavage fluid (BALF) from ABCA3-deficient infants who underwent lung transplantation in infancy had diminished surface tension–lowering properties and was markedly reduced in DSPC and phosphatidylglycerol (PG) content compared with controls,[128] and similarly altered surfactant lipid and protein profiles were found in lung fluid samples from BALF from ABCA3- and SP-B–deficient subjects in another study.[129,130] Targeted disruption of either *sftpb* or *abca3* in genetically engineered mice resulted in a neonatal lethal respiratory phenotype.[57–60,131] In addition, the phospholipid profiles of *abca3* null mice were markedly abnormal, with very low levels of DSPC and PG.[57,59] These observations support an essential role for ABCA3 in the transport of lipids important for surface tension reduction.

Secondary changes in the metabolism of other surfactant components have been observed in lung tissue and fluid from SP-B–, and to less extent ABCA3-, deficient infants that likely further complicate the extent of surfactant deficiency. In SP-B deficiency, there is an accumulation of aberrantly processed SP-C peptides that result from incomplete processing of the SP-C precursor (proSP-C) to mature SP-C.[120,122,132] This block in SP-C processing may result in SP-B–deficient infants also being deficient in mature SP-C, and the partially processed proSP-C peptides have reduced surface tension–lowering activity, further contributing to surfactant dysfunction in SP-B–deficient infants.[133] This appearance is consistent with a role for SP-B in membrane fusion of smaller vesicles to pack and organize lipid bilayers into lamellar bodies.[134] The final processing steps for mature SP-C occur in lamellar bodes, and the failure to properly form this intracellular organelle is therefore probably related to the SP-C processing abnormality. The abnormal lamellar body formation in ABCA3 deficiency may also relate to abnormally processed proSP-C intermediates observed in lungs of affected infants, although such peptides have not been as abundant or consistently observed as in SP-B–deficient infants.[135]

The pathophysiology underlying the relatively milder phenotype of some ABCA3-deficient children who do not exhibit findings of neonatal surfactant deficiency and who present later in life with lung disease is less clear. One potential mechanism is that some mutations allow for partial ABCA3 function. A mutation (p.Glu292Val or p.E292V) that has been found in multiple unrelated subjects with a relatively milder phenotype has been shown to cause partially impaired lipid transport compared with wild-type ABCA3 in vitro.[136,137] In addition, children with genotypes that are predicted to completely preclude ABCA3 expression have almost universally had a severe phenotype with neonatal-onset disease and early lethality, whereas children with relatively milder disease have had genotypes in which at least one mutation could allow for some ABCA3 expression and function.[23] Other mechanisms for later lung injury may also be important. Some mutations may also be associated with endoplasmic reticulum (ER) stress and trigger the unfolded protein response (UPR), contributing to AEC2 injury and chronic lung disease, and ABCA3 may have a role in protecting AEC2s from cholesterol toxicity.[138,139] More than 250 *ABCA3* mutations scattered throughout the gene have been reported to date.[19–21,23,90,117,121,124,128,135,140–150] Type I mutations are not properly routed to distal cellular compartments, and type 2 mutations result in reduced ATP hydrolysis and/or impaired lipid transport.[136,151,152] This classification scheme does not incorporate nonsense and frameshift mutations, which are likely associated with unstable transcripts, and it is likely to evolve as our understanding of normal ABCA3 cell biology increases.

Although ABCA3 and SP-B deficiency generally are recessive disorders with mutations on both alleles (biallelic) needed to manifest disease, in some circumstances a mutation on just one allele (monoallelic) may contribute to lung disease. Preterm and near-term infants with monoallelic ABCA3 mutations may be at higher risk for developing RDS,[24,153] and heterozygosity for an *ABCA3* mutation may modify the course of *SFTPC*-related diseases.[90,128] Adult carriers for the most common *SFTPB* mutation appear to be at higher risk for development of obstructive lung disease, particularly in conjunction with smoking exposure.[15] Genetically engineered mice with one null *sftpb* allele were more susceptible to pulmonary oxygen toxicity than their wild-type littermates,[154] and mice who were genetically engineered to be able to turn off their SP-B production developed lung disease when their SP-B levels fell to less than 20%–25% of normal adult levels.[155] These observations suggest that a critical level of SP-B is needed for normal lung function and that having a loss-of-function *SFTPB* mutation on only one allele could thus be a risk factor for the development of lung disease if other factors further reduce SP-B expression.[156,157] Similarly, mice with one inactivated *abca3* allele were also observed to be more susceptible to pulmonary oxygen injury.[158] Finally, patients with only one *ABCA3* mutation and both severe neonatal lung disease and ILD have been recognized.[159,160] It is possible that these patients had a mutation on the other allele that escaped detection. Alternatively, a single *ABCA3* mutation may predispose individuals to lung disease in conjunction with other genetic or environmental mechanisms. There is evidence that ABCA3 expression may be monoallelic at a cellular level, and thus in individuals with heterozygous *ABCA3* mutations unequal expression of the abnormal allele within a population of AEC2s could result in abnormal surfactant metabolism and disease.[161]

The pathophysiology of lung disease due to *SFTPC* mutations is complex and incompletely understood. Lack of mature SP-C could plausibly contribute to the lung disease. Mice unable to produce SP-C due to targeted inactivation of *sftpc* develop progressive air space enlargement and interstitial inflammation as they age in a strain-dependent fashion.[162,163] The variability depending upon the genetic background of the null mice indicates that genetic modifiers are likely important in the development of SP-C–related lung disease. Mutations in other genes important in surfactant metabolism, such as *ABCA3*, may modify the severity of lung disease due to *SFTPC* mutations.[90,91] Human lung disease resulting from null mutations on one or both alleles of *SFTPC* has not been reported. Familial ILD, associated with markedly reduced SP-C expression in lung tissue and undetectable SP-C in BALF, has been observed, but disease in this family was subsequently found to be due to *NKX2-1*.[38,164] In support of SP-C deficiency as a mechanism for disease, a lack of both proSP-C and mature SP-C has been observed in the lung tissue of subjects with some *SFTPC* mutations.[78,165,166] SP-C self-associates in the secretory pathway, and thus a dominant negative effect on SP-C production from the abnormal proSP-C that results from a mutation could account for the lack of mature SP-C.[167] Subsequent studies in which an *SFTPC* mutation that resulted in the skipping of an entire exon (Δexon4) was expressed in in vitro systems provided support for this mechanism, as the abnormal proSP-C was not processed to mature SP-C, not routed appropriately in the cells, and was rapidly degraded.[165,168,169]

*SFTPC* mutations may cause lung disease due to toxicity from abnormal proSP-C, a "gain-of-toxic-function" mechanism. All of the *SFTPC* mutations associated with human lung disease reported to date are predicted to result in the production of an abnormal proprotein, which is likely misfolded.[170] The exposure of hydrophobic epitopes in the misfolded proprotein may be directly toxic to AEC2s, especially if produced in sufficient amounts to be unable to be efficiently degraded through the proteasome pathway. Proteasome dysfunction may also inhibit expression of other SP, further contributing to surfactant dysfunction.[171] Accumulation of misfolded protein within the ER may trigger the UPR and eventually caspase activation and apoptosis of AEC2s.[168,169,172–174] SP-C lung disease may thus represent a conformational disease with accumulation of misfolded protein in the cell causing secondary cellular toxicity.[170] Increased levels of UPR components and caspase activation have also been observed in lung tissue from patients with pulmonary fibrosis not due to *SFTPC* mutations, suggesting that protein misfolding may be a more general mechanism for AEC2 injury.[175,176]

Other mechanisms may also contribute to the pathophysiology of lung injury with *SFTPC* mutations. ProSP-C intermediates are normally routed to lamellar bodies, but with some mutations, particularly those located in the bridging domain between the mature SP-C peptide and the BRICHOS domain, proSP-C is routed to the plasma membrane and then internalized through an endosomal pathway. Accumulation of intermediates and a block in autophagy may then contribute to cellular injury.[165,166,177] With multiple mechanisms that may be dependent upon the location and nature of a specific mutation, different strategies aimed at correcting folding or routing of specific mutations may be needed.

Because TTF-1 is essential for the expression of SP-B, SP-C, and ABCA3, it is not surprising that reductions in the amount of this transcription factor could result in the phenotypes of RDS (surfactant deficiency) and ILD (surfactant dysfunction). Complete loss of function of one *NKX2-1* allele has been demonstrated both by complete gene deletions and *in vitro* studies of mutations demonstrating impaired DNA binding or decreased transcription of reporter genes; a gain-of-function mechanism with overexpression of downstream genes is also possible.[37,95,96] It is unknown whether lung disease results primarily through the reduction of one surfactant component (such as SP-B or ABCA3) below a critical level needed for normal lung function or a combination of reduced levels of more than one protein. Evaluation of SP expression has been evaluated in a limited number of subjects with *NKX2-1* mutations with variable findings. Diminished immunoreactivity for SP-A and ABCA3 but robust staining for SP-B and proSP-C were observed in a subject with a *NKX2-1* deletion.[118] Because SP-A is also regulated by TTF-1, reductions in this pulmonary collectin may account for the observation of recurrent pulmonary infections in some subjects. Severely reduced expression of another pulmonary collectin, SP-D, was observed in a child with a *NKX2-1* mutation who developed respiratory failure after a viral infection.[38] Reduced amounts of both proSP-C and mature SP-C were observed in three members of the same family with a *NKX2-1* missense mutation.[38,164] Intriguingly, a missense variant of *NKX2-1* has been identified that segregated with familial lung disease of a different pulmonary phenotype, that of neuroendocrine cell hyperplasia of infancy (NEHI).[178,179] The lung histopathology and immunostaining pattern in one affected family member were not typical for surfactant dysfunction. Combined with observations of variable expression of SP in lung tissue from other subjects with *NKX2-1* mutations, this observation suggests the hypothesis that the primary pulmonary phenotype due to *NKX2-1* mutations may relate to the downstream target genes whose expression is most affected by the mutated allele. Because TTF-1 is also important for the expression of many other genes in the lung important in lung physiology (examples include the club cell secretory protein, and the genes encoding the amiloride-sensitive sodium channel), this may explain some of the diverse phenotypic features associated with *NKX2-1* mutations. Finally, the mechanisms for the variable severity of disease associated with *NKX2-1* mutations are unknown but may relate to either genetic variants in *NKX2-1* affecting expression level of the remaining functional allele, or factors controlling the expression and function of the multiple other transcription factors (including GATA6, FOXA2, C/EBP$\alpha$, NFAT) needed for SP and ABCA3 gene expression.

## Disorders of Surfactant Clearance

PAP is a syndrome that occurs in a heterogeneous group of diseases and is defined histopathologically by the presence of a finely granular, lipoproteinaceous material filling pulmonary alveoli and terminal airspaces. The accumulated material stains with eosin and periodic acid–Schiff (PAS) reagent has biochemical and ultrastructural features identical to surfactant and frequently contains cholesterol “needles” and cellular debris. Depending on the underlying PAP-causing disease, alveolar distortion and/or fibrosis may or may not be present. The relative proportion of these specific histologic features present varies markedly among the diseases causing PAP (i.e., the histopathologic pattern depends on the pathogenesis involved).

The pathogenesis of PAP remained obscure for nearly four decades after its initial description in 1958 because research was hampered by its rarity and the heterogeneity of diseases causing the syndrome.[45,180] Most cases occur in previously healthy individuals without significant environmental pulmonary exposure other than smoking, referred to as idiopathic or acquired PAP. However, PAP also occurs in association with various underlying diseases, termed secondary PAP (see later). A serendipitous but critical pathogenic clue for the common idiopathic form was the observation that mice deficient in GM-CSF or a component of its receptor developed a phenotype virtually identical to idiopathic PAP in humans.[8,9,106,107] Although PAP caused by GM-CSF deficiency has not yet been reported in humans, a second pathogenic clue was the observation that idiopathic PAP is specifically associated with high levels of neutralizing autoantibodies against GM-CSF.[102,181,182] Passive transfer studies established that GM-CSF autoantibodies cause PAP by blocking GM-CSF signaling to alveolar macrophages,[183] which is required to stimulate surfactant clearance.[183] Additional pathogenic insight was provided by the identification of hereditary PAP in mice and children due to genetic mutations in *CSF2RA* and *CSF2RB,* which block GM-CSF signaling by impairing GM-CSF receptor function.[46,49,51,52,104]

# Clinical Features of Surfactant Production Disorders

## Presentation, Symptoms, and Physical Findings

Two typical clinical presentations are seen in children with surfactant production disorders. The first is a neonatal presentation with diffuse lung disease in a full-term infant that is like that of a premature infant with RDS. Clinical signs include tachypnea, grunting, nasal flaring, retractions, and cyanosis in room air and may develop within minutes to hours after birth. Affected infants rapidly progress to hypoxemic respiratory failure, often needing high-frequency ventilation and support with extracorporeal membrane oxygenation in the past. This is the usual presentation for children with SP-B deficiency and many with ABCA3 deficiency. Children with *NKX2-1* mutations may also present in a similar fashion. Newborns with *SFTPC* mutations may have a similar presentation, but the initial lung disease is usually not as severe as seen in SP-B or ABCA3 deficiencies and most individuals with *SFTPC* mutations present later in life, ranging from early infancy until well into adulthood.

The other clinical presentation of children with surfactant production disorders is with nonspecific respiratory symptoms and signs, which may be acute, subacute, or chronic in onset, and this is typical for children with *SFTPC* mutations. Respiratory symptoms in children (and adults) with *SFTPC* mutations include cough, difficulty breathing, and exercise intolerance, and signs include tachypnea, crackles, digital clubbing, pectus excavatum, failure to thrive, and need for supplemental oxygen and have been summarized in several clinical studies.[29,75,88,184] The age of onset of symptoms is highly variable in individuals with *SFTPC* mutations, with some infants developing very early in life and others remaining asymptomatic well until adulthood.[29,31,78,85,184] Importantly, infants and children with very severe disease who require aggressive supportive measures, including mechanical ventilation, may show steady but gradual improvement over time, although the disease does not resolve.[185] Clinical presentation of lung disease in some children has apparently been triggered or exacerbated by viral infections.[31,184] Cells in culture that stably expressed a *SFTPC* mutation at low levels did not have overt signs of cellular toxicity but died when exposed to respiratory syncytial virus (RSV), providing a potential mechanism for such a genetic-environmental interaction.[186]

Although initial reports of children with ABCA3 deficiency focused on severe neonatal disease, it is now recognized that ABCA3 deficiency may result in milder lung disease and later presentation, including as adults.[117,144–146,187] Affected children may not have exhibited any symptoms or signs of lung disease in the neonatal period or have had apparently transient or mild lung disease in the neonatal period but subsequently developed findings like those of children with *SFTPC* mutations.[19,23,117,144,188]

## Imaging, Pulmonary Function Testing, and Laboratory Findings

The typical initial chest radiographic findings in neonates with surfactant production disorders resemble those of preterm infants with RDS, with diffuse granular alveolar and interstitial infiltrates, along with air bronchograms. Air leak (pneumothorax, interstitial emphysema) is common. Over time, infiltrates become coarser but do not resolve. In the early phase of the disease, HRCT images show diffuse ground-glass opacities with interlobular thickening. In such infants, if supported with long-term ventilation as a bridge to lung transplantation, later imaging studies may show areas of cystic dilatation and interstitial fibrotic changes.[189] In older children, radiographic findings depend upon severity of disease, but ground-glass opacities are common, as are peripheral cysts seen on HRCT.[188]

Because most affected infants succumb early in life, there are no reported studies of pulmonary function tests in SP-B–deficient infants. There are limited data on pulmonary function testing (PFT) findings in infants and older children with other surfactant production disorders. Infant PFTS in two children with *SFTPC* mutations demonstrated a restrictive pattern, and a restrictive pattern was also noted in older children with ABCA3 mutations.[144,190] In a population-based study, carriers for the 121ins2 mutation were found to be at risk for reduced lung function as adults, especially in conjunction with smoking.[15]

Currently there are limited data on the utility of other laboratory tests and biomarkers for surfactant production disorders. Serum lactate dehydrogenase (LDH) levels may be elevated reflecting ongoing epithelial cell injury. Serum KL-6, a mucin produced by alveolar epithelial cells, may be a useful serum biomarker, but the availability of clinically available assays is limited.[191]

## Diagnosis and Differential Diagnosis

The identification of genetic abnormalities as causes of surfactant production and clearance provides the means for diagnosis of these rare conditions through noninvasive genetic or serologic testing. Although specific therapies may not be available, timely diagnosis is important to provide accurate counseling regarding prognosis, assessment of risk for other family members, and recurrence risk for future pregnancies. Clinical algorithms for a diagnostic approach to suspected genetic causes of surfactant production and clearance have not been formally evaluated, but the typical clinical presentations of each disorder may provide guidance as to which patients to evaluate.[192–194]

Diffuse lung disease in a full-term infant with radiographic features of surfactant deficiency should prompt consideration of a genetic disorder of surfactant production, particularly due to mutations in *SFTPB, ABCA3,* and *NKX2-1.* Gestational age less than

38 weeks, male gender, operative delivery (especially elective), and white race are known risk factors for RDS in near-term infants.[26,195] Absence of these risk factors, failure to improve after the first 7–10 days of life, or a family history of severe neonatal lung disease should increase suspicion for a genetic mechanism for the lung disease. Other diagnoses to be considered include infection (both viral and bacterial), cardiac disease (especially total anomalous pulmonary venous return), pulmonary lymphangiectasia, pulmonary hypoplasia, and alveolar capillary dysplasia with misalignment of the pulmonary veins.

The diagnosis of genetic disorders of surfactant production and clearance should be considered in older children and young adults who present with what has been termed “chILD syndrome.”[192–194] Criteria for chILD syndrome include three of four of the following: (1) respiratory symptoms, including cough, rapid breathing, shortness of breath, difficulty breathing, or exercise intolerance; (2) respiratory signs, including tachypnea, adventitial sounds, retractions, digital clubbing, pectus excavatum, failure to thrive, or acute respiratory failure; (3) hypoxemia while breathing room air; and (4) diffuse abnormalities on chest imaging. Other both rare and more common causes of lung disease should first be excluded, including cystic fibrosis, infectious causes, immunodeficiency, bronchopulmonary dysplasia, congenital heart disease, primary ciliary dyskinesia, and chronic aspiration.[194] The absence of a family history of lung disease should not preclude evaluation because de novo *SFTPC* and *NKX2.1* mutations may cause sporadic disease and ABCA3 deficiency is inherited as an autosomal recessive disorder. Neurologic findings, including hypotonia or developmental delay, should prompt consideration of an *NKX2.1* mutation or deletion, as should hypothyroidism. Children or adolescents with insidious onset of disease and diffuse alveolar infiltrates after the neonatal period, or who have biopsy findings consistent with alveolar proteinosis, should be evaluated for serum GM-CSF autoantibodies, and/or *CSF2RA* and *CSF2RB* mutations.

## Genetic Testing

The diagnosis of a surfactant production disorder is made through genetic testing, which is available in certified diagnostic laboratories (www.genetests.org).[22] The availability of panels using next-generation sequencing (NGS) methods allows for simultaneous analysis of multiple other genes that may result in similar phenotypes. Such panels may also detect copy number variants, and entire deletions of *NKX2-1,* as well as large deletions in *SFTPB* and *ABCA3,* have been recognized.[38,70,196,197] For SP-B and ABCA3 deficiencies a diagnosis is established by finding of pathogenic or likely pathogenic mutations on both alleles. Testing of the parents is advisable both to confirm segregation of the variants and determine that they are on opposite alleles when two different mutations are found, or a homozygous mutation is found to confirm that both parents are carriers, as opposed to a rare mechanism such as uniparental disomy, which would alter the recurrence risk.[23,147,197,198] For *SFTPC* and *NKX2-1* a diagnosis is established with the finding of a pathogenic or likely pathogenic mutation on one allele.

There are important limitations to genetic testing. Such testing is not 100% sensitive; functionally significant variants in untranslated regions that affect gene expression or mRNA splicing will not be detected. Gene deletions, insertions, duplications, and rearrangements may be missed unless specific methods are used to look for such variants. In addition, interpretation of results may be difficult, particularly for what are called “variants of uncertain significance” (VUS), where it is unknown whether a variant represents a pathogenic or benign sequence variant. As the number of genes included in NGS panels increase, the likelihood of finding a VUS in one or more genes increases. It also may be difficult to determine whether subjects with recessive disorders in whom only one mutation is identified are affected with a mutation that escaped detection on the other allele or are simply carriers with a pathogenic variant unrelated to the cause of their lung disease. The turnaround time for genetic testing can be several weeks, which may be inadequate in a patient who is unstable or has rapidly progressive disease. Finally, genetic testing is expensive, the costs for such testing may not be covered by insurance, and it may be impractical for patients to pay for the testing out of pocket.

## Lung and Serum Biomarkers

Levels of mature SP-B protein are usually undetectable in tracheal aspirate (TA) or BALF in children with SP-B deficiency.[66,130] In addition, the presence of aberrantly processed proSP-C peptides in the TA or BALF is a marker for the disorder.[132] However, assays for these proteins in biologic samples are not currently available in diagnostic labs, and there may be overlap in the findings with those of children with other genetic surfactant production disorders, so assays of TA or BAL fluid may not be helpful in making the diagnosis.[130,135]

Serum GM-CSF autoantibody testing is now commercially available (https://www.cincinnatichildrens.org/service/r/rare-lung/professionals/pap-lab) and is particularly useful in identifying individuals with autoimmune PAP and has a sensitivity and specificity approaching 100%. This test is recommended for all adults, adolescents, and older children with the typical history and radiographic findings of PAP. Identification of specific biomarkers in blood or lung fluid could provide useful tools for diagnosis or disease progression.[46,191] For example, increased levels of SP in either lung fluid or serum may provide a simple and useful means to monitor lung disease severity in these disorders. However, such tests are currently available only in research protocols and are of uncertain sensitivity and specificity for surfactant-related lung diseases.[135] In contrast, the finding of an elevated serum GM-CSF level and a negative serum GM-CSF autoantibody level in a patient with hereditary PAP caused by *CSF2RA* or *CSF2RB* mutations appears to be a useful screening diagnostic test for this group of genetic diseases of surfactant homeostasis.

## Lung Histopathology

Lung biopsy has a potentially important role in the diagnosis of ILDs but has distinct limitations in the differential diagnosis of PAP-causing diseases. Lung histopathology may help to distinguish disorders of surfactant clearance from disorders of surfactant production, based in part on the presence and level of disruption of alveolar architecture. However, lung histopathology does not distinguish the relatively common form of autoimmune

PAP from hereditary PAP caused by *CSF2RA* or *CSF2RB* mutations, nor can it distinguish between the latter two. Sampling error can be an important limitation for diagnosis based on lung histopathology even when tissues are obtained based on surgical biopsies. This is particularly true in diseases with a heterogeneous, "geographic" involvement of the lungs. When lung biopsies are indicated, the tissues should be obtained and handled appropriately according to published guidelines to optimize diagnostic yield and should include obtaining electron microscopy and frozen tissue.[199]

Tissue examination can also be used for diagnosis, particularly when immunohistochemistry and electron microscopy augment routine histologic examination. Histologic findings overlap with those of other surfactant dysfunction disorders and include AEC2 hyperplasia, interstitial thickening with mesenchymal cells and fibrosis in advanced stages of the disease, and variable amounts of lipoproteinaceous material accumulating in alveolar macrophages and filling distal airspaces. Absent staining for SP-B is suggestive of SP-B deficiency, but this is not necessarily specific because absent staining for SP-B has also been observed in some cases of ABCA3 deficiency. Intense staining of extracellular material with antibodies directed against amino-terminal epitopes of proSP-C appears to be indicative of SP-B deficiency, but such staining may not be available in many labs. Electron microscopy (EM) findings of abnormal lamellar bodies that are disorganized with multivesicular inclusions have been consistently observed in the lungs of SP-B–deficient infants. Ultrastructural examination of lung tissue obtained at biopsy or autopsy may also be helpful in establishing the diagnosis of ABCA3 deficiency and distinguishing it from other inborn errors of surfactant metabolism if no normal lamellar bodies are observed and only the characteristic small, "fried egg–" appearing organelles are present. A caveat is that most of the reported ultrastructural studies were in children with the most severe form of ABCA3 deficiency, and ultrastructural findings may be more variable in children with milder disease. EM requires proper handling of the tissue because the lipid components of lamellar bodies are extracted with many fixatives and EM is not routinely performed on lung tissue samples. Thus, although tissue examination may be strongly suggestive, genetic testing is needed to establish a definitive diagnosis.

## Management, Treatment, and Prognosis

As a common phenotype for surfactant production disorders is that of RDS, such newborns are often treated initially with exogenous surfactant. SP-B– or ABCA3-deficient infants may show some initial improvement after treatment with exogenous surfactant, but in SP-B deficiency the disease is invariably progressive with diminished responses to subsequent doses. The course of children with ABCA3 deficiency is more variable, with some acting similarly to those with SP-B deficiency, whereas others may improve considerably after one or two doses, although the disease does not resolve completely. As surfactant deficiency underlies part of the pathophysiology of *NKX2-1* mutations, a trial of exogenous surfactant is not unreasonable in affected infants. With *SFTPC* mutations, because the pathophysiology of the lung disease depends more upon direct cellular injury as opposed to deficiency of surfactant lipids or proteins, there is less rationale for surfactant augmentation therapy. However, in the absence of a family history, a diagnosis is usually not established at the time surfactant therapy is considered.

Currently there are no specific treatments for children with surfactant production disorders. Thyroid hormone replacement is indicated in those patients with evidence of hypothyroidism, but specific therapies for the lung disease due to *NKX2-1* mutations have not been evaluated. ABCA3 gene transcription is increased by glucocorticoids in vitro, providing a rationale for treatment with steroids to augment any remaining gene function, but clinical evidence for the efficacy of steroids for this condition is limited.[19,200] Similarly, rare children with partial SP-B deficiency, which results from mutations that allow for some SP-B production and can be associated with intermediate survival, may show improvement with corticosteroids.[156] Treatment of *SFTPC* mutations has also included corticosteroids, as well as hydroxychloroquine, and azithromycin, and these agents have also been used in treating ABCA3 deficiency. Anecdotal reports provide evidence that these drugs may help some patients with these disorders, with worsening of disease observed when the drug was stopped and improvement observed when drug therapy resumed, but not all affected subjects respond.[29,84,184,201–204] The efficacy of these agents is uncertain and complicated by the variability in the natural history of the disease, and the possible mechanisms of action are also unclear.[202] The use of drugs to correct and facilitate protein folding and trafficking within AEC2s may represent a future approach to the treatment of these disorders similarly to current approaches for treating some mutations responsible for cystic fibrosis.[165,205] Advances in gene-editing approaches may represent another novel therapeutic option in the future.[206] The generation of animal models will be important to test both existing and novel therapies.

Lung transplantation has been performed in children with end-stage lung disease from surfactant production disorders, with results comparable to those of similarly age-matched subjects.[207,208] Complete deficiency of SP-B is generally lethal, and the lung disease in ABCA3 deficiency is often severe and invariably progressive. ABCA3 genotypes involving biallelic mutations predicted to completely preclude ABCA3 expression have to date been invariably associated with a poor prognosis.[23] *ABCA3* genotype may thus be helpful in deciding upon which ABCA3-deficient children are early candidates for lung transplantation, although caution is warranted because siblings with the same genotype may have very different clinical courses.[187,209,210] In contrast, no consistent association of SFTPC genotype with clinical course has been observed.[29] The variability in the natural history of lung disease due to *SFTPC* and *NKX2-1* mutations complicates the decision for lung transplantation for these disorders, particularly with the potential for considerable improvement with supportive care for SFTPC mutations.[211]

Because SP-B and ABCA3 deficiencies are autosomal recessive conditions, there is a 25% recurrence risk for future children born to the parents of an affected child, and they should be referred for formal genetic counseling. Identification of responsible mutations allows for antenatal diagnosis and potentially even preimplantation genetic diagnosis such that an unaffected child may be born after in vitro fertilization. Because familial disease due to *SFTPC* or *NKX2-1* mutations is inherited in a dominant pattern, there is a 50% recurrence risk should a parent carry the same mutation found in the child. As de novo mutations in both genes may cause sporadic disease, the recurrence risk may be much lower if neither parent is found to carry the mutation, but the risk is not zero, owing to the possibilities of germline mosaicism or nonpaternity. A complicating factor in genetic testing of the parents of children with these disorders, particularly *SFTPC,* is that an asymptomatic parent may be found to have a mutation, with important implications for their health, reinforcing the need for formal genetic counseling when undertaking such testing.

Whole lung lavage is currently the standard therapy for autoimmune PAP; it works well in most patients and improves survival and quality of life. Occasionally, or possibly late in the course of disease, whole lung lavage therapy can become less effective. Over the past decade, a series of small clinical studies have demonstrated that GM-CSF augmentation can be effective in treating this disease. However, neither the indications for use, route or timing of administration, dosage, or duration of therapy have been evaluated in prospective clinical trials. Thus further studies are needed. Anti-CD20 therapy using rituximab has been reported in a very limited number of patients with this disease and more studies are needed to evaluate the safety and efficacy of this potential therapy.

The number of patients with PAP caused by GM-CSF receptor defects identified to date is small, and therefore information regarding the natural history of these disorder remains unclear. Whole lung lavage has been successfully used to ameliorate the severity of the pulmonary symptoms, but, because the underlying defect remains, in most cases therapy is required on a periodic basis.[46] As serum GM-CSF levels are already elevated and patient macrophages do not respond to GM-CSF in vitro, exogenous GM-CSF seems unlikely to benefit most of these patients because components of the GM-CSF receptor are absent. However, in cases in which impaired GM-CSF signaling is due to decreased GM-CSF binding affinity rather than the absence of the receptor itself, GM-CSF augmentation therapy to increase the GM-CSF concentration may overcome the signaling defect and restore surfactant clearance by alveolar macrophages.[46,49] Clinical trials to evaluate inhaled GM-CSF as potential therapy thus warrant consideration. Because alveolar macrophages are bone marrow derived and based upon experiments in βc receptor–deficient mice, bone marrow transplantation may be curative for this group of disorders.[212] Cell- and gene-transfer–based therapeutic strategies are also in development for these disorders. Transplantation of pulmonary macrophages shows promise in reversing the phenotype of hereditary PAP in a mouse model.[213]

## Summary

Single gene defects have been identified that disrupt surfactant production and metabolism (ABCA3, SFTPB, SFTPC, NKX2-1), as well as surfactant clearance (CSF2RA, CSF2RB). The phenotypes of these disorders include acute neonatal respiratory failure, progressive diffuse childhood lung disease, pulmonary fibrosis in adults, and dyspnea and respiratory failure from surfactant accumulation in children, adolescents, and adults. There is considerable overlap in the clinical features and lung pathology findings associated with these disorders, which are summarized in Table 57.1. Genetic testing is needed for specific diagnosis, which may obviate the need for lung biopsy in some patients. Specific therapies for these disorders are not currently available. Lung transplantation has been performed for disorders of surfactant production. Disorders of surfactant clearance result from macrophage dysfunction, and bone marrow transplantation is a potential therapy. Given the complexity of the surfactant system, it is likely that other genetic disorders disrupting surfactant metabolism will be identified as causes of rare lung diseases, providing new insights into normal surfactant metabolism and suggesting candidate genes contributing to the pathogenesis of more common lung diseases such as neonatal RDS.

### Table 57.1

**Features of Hereditary Disorders of Surfactant Production and Clearance**

| **OMIM Name** | **SP-B Deficiency SMDP1** | **ABCA3 Deficiency SMDP3** | **SP-C Dysfunction SMDP2** | **T In B Lu** |
|---|---|---|---|---|
| Epidemiology | Extremely rare, <1 in 1 million | Rare; incidence estimate 1 in 3500 to 1 in 20,000 | Rare; incidence and prevalence unknown | Rare; preva |
| Etiology | | | | |

# Pulmonary Involvement in the Systemic Inflammatory Diseases of Childhood

*Sharon D. Dell BEng, MD, Rayfel Schneider MBBCh, Rae S.M. Yeung MD, PhD, FRCPC*

## Overview of Chapter

In this chapter, we will highlight pulmonary manifestations of the systemic inflammatory diseases of childhood. We will focus on the diseases that are either common in the pediatric rheumatology clinic or those that commonly involve the lungs. These include juvenile idiopathic arthritis (JIA), the connective tissue diseases (systemic lupus erythematosus [SLE], scleroderma [SSc], juvenile dermatomyositis [JDM], and mixed connective tissue disease

[MCTD]), vasculitides (especially granulomatosis with polyangiitis [GPA]), and sarcoidosis. Clinically significant pulmonary involvement due to systemic inflammatory disease is rare in the pediatric setting. However, it is important for the pediatric pulmonologist to be familiar with this topic for two reasons: (1) pulmonary involvement may be associated with high morbidity and mortality in this population and (2) pulmonary disease may be the predominant initial clinical presentation in a subset of these patients. The systemic inflammatory diseases most frequently encountered by the pediatric pulmonologist include GPA, SLE, SSc, and MCTD. Symptom patterns along with specific autoantibody serological tests are most useful for diagnosing the underlying systemic inflammatory disease (Table 58.1). Pulmonary involvement in these cases can often be a difficult diagnostic dilemma, as lung toxicity due to potent pharmacotherapies and opportunistic infections must be considered alongside the possibility of the lung being a target organ of the underlying inflammatory disease. Lung disease may involve any compartment of the lung (chest wall, pleura, airways, parenchyma, and vasculature), and often more than one pulmonary etiology may be present simultaneously (e.g., pulmonary fibrosis and chest wall restriction). Although there is certainly overlap in the pulmonary manifestations between different diseases, certain patterns are recognized with greater frequency in some entities (Table 58.2). For example, interstitial lung disease (ILD) and pulmonary arterial hypertension (PAH) are characteristic of systemic sclerosis, while pleuritis and pleural effusions are characteristic of JIA and SLE and would be very unusual in the context of JDM. For the purposes of classifying lung disease in this chapter, ILD will be defined as a clinical diagnosis of “pulmonary fibrosis” or a lung biopsy histopathological pattern of nonspecific interstitial pneumonitis (NSIP), usual interstitial pneumonitis (UIP), lymphocytic interstitial pneumonitis (LIP), bronchiolitis obliterans (BO) organizing pneumonia (BOOP, also known as cryptogenic organizing pneumonia), or diffuse alveolar damage (DAD).[1] Treatment of lung disease is specific to the underlying systemic disease and is often effective at reducing pulmonary morbidity. Prognosis is variable and dependent on the severity of the disease and its response to therapy. Disease progression is monitored by following symptoms, particularly dyspnea, the use of routine pulmonary function and exercise testing, and high-resolution computed tomography (HRCT) imaging. The role of serological biomarkers to detect and monitor progression of ILD, particularly SP-D and KL-6, is an area of active investigation. As the prognosis for the systemic inflammatory diseases improves, increasing emphasis is being placed on early detection and treatment of lung disease.

## Table 58.1

### Commonly Requested Serologic Tests for Selected Pediatric Systemic Inflammatory Diseases With Possible Pulmonary Involvement

| Autoantibody Serologic Test | Disease Entity | Comments |
|---|---|---|
| ANA | Nonrheumatic disease | Present in 10% of normal children; may occur with infection, drug, malignancy |
| | SLE | Present in virtually 100% of SLE, but not specific |
| | Oligoarticular JIA | Present in 60%–80%, marker for uveitis |
| | JDM | Present in 50%–75% |
| | SSc | Present in 90% systemic sclerosis, 50% of localized scleroderma |
| | MCTD | Present in 100%, speckled pattern and very high titer |
| Anti-dsDNA | SLE | Present in 60%–90%; very specific; titer correlates with disease activity |
| Anti-Sm | SLE | Present in 25%–40%; very specific; correlates with renal disease |
| Anti-Ro/anti-La | SLE, Sjögren's syndrome | |
| Anti-RNP | SLE, MCTD, scleroderma | When present in very high titer, suggests MCTD |
| Anticardiolipin | SLE, Antiphospholipid antibody syndrome | May also occur in infection and malignancy; IgG isotype associated with thrombosis |
| Anti-Jo-1 | Myositis | Rare in children; marker for ILD in adult dermatomyositis |
| Anti-Scl-70 | SSc | Marker for severe lung disease |
| Anticentromere | Limited SSc | Rare in children; marker for late development of pulmonary hypertension |
| ANCA<br>■ PR3 (antiproteinase 3 antibody)<br>■ MPO (antimyeloperoxidase antibody | Vasculitides<br>GPA<br>MPA | May also occur with SLE and inflammatory bowel disease<br>Sensitive (>90%) and specific for GPA<br>Sensitive (~70%) and specific for MPA |
| Rheumatoid factor | RF+ polyarticular | Poor sensitivity and specificity for JIA; when |

| | | |
|---|---|---|
| | JIA | present in patients with JIA it is associated with severe disease (usually adolescent females). Also positive in 50% GPA. |

*ANA,* Antinuclear antibody; *ANCA,* antineutrophil cytoplasmic antibody; *GPA,* granulomatosis with polyangiitis; *IgG,* immunoglobulin G; *ILD,* interstitial lung disease; *JDM,* juvenile dermatomyositis; *JIA,* juvenile idiopathic arthritis; *MCTD,* mixed connective tissue disease; *MPA,* microscopic polyangiitis; *SLE,* systemic lupus erythematosus; *SSc,* scleroderma.

## Table 58.2

## Summary of Pulmonary Manifestations of Systemic Inflammatory Disease in Children

| | JIA | SLE | JDM | SSc | MCTD | Sarcoidosis | GPA | MPA |
|---|---|---|---|---|---|---|---|---|
| Frequency at initial presentation[a] | + | ++ | + | +++ | + | +++ | +++ | + |
| Frequency during disease course[b] | + | +++ | + | +++ | +++ | +++ | +++ | ++ |
| Chest wall/diaphragm[c] | + | + | +++ | + | + | − | − | − |
| Pleural disease[d] | ++ | +++ | − | + | ++ | + | + | − |
| Large airway lesions[e] | − | − | − | − | − | ++ | ++ | − |
| Bronchiectasis | + | + | − | + | − | + | + | − |
| Acute pneumonitis[f] | + | ++ | + | − | − | − | − | − |
| ILD[g] | + | + | + | +++ | ++ | + | − | − |
| Pulmonary granulomas | − | − | − | − | − | +++ | +++ | − |
| Vasculitis/DAH[i] | + | + | − | + | + | − | ++ | +++ |
| Pulmonary hypertension | − | + | + | ++ | ++ | − | − | + |
| Thrombosis | − | ++ | − | − | − | − | + | − |

[a] Pulmonary involvement at initial presentation of systemic inflammatory disease.

[b] Frequency of pulmonary involvement during disease course.

[c] Includes respiratory muscle weakness and diaphragm dysfunction.

[d] Pleuritis and/or pleural effusion.

[e] Upper airway and endobronchial lesions and/or stenosis visible on bronchoscopy.

[f] A clinical diagnosis with acute onset of fever, tachypnea, hypoxia, and pulmonary infiltrates with or without pleural effusion on chest imaging, in the absence of infection and usually responding quickly to antiinflammatory treatment.

[g] Includes clinical diagnosis of “pulmonary fibrosis” and histopathological diagnosis of usual interstitial pneumonia (UIP), nonspecific interstitial pneumonitis (NSIP), lymphocytic interstitial pneumonitis (LIP), bronchiolitis obliterans organizing pneumonia (BOOP), and diffuse alveolar damage (DAD).

[i] *DAH,* diffuse alveolar hemorrhage.

*GPA,* Granulomatosis with polyangiitis; *ILD,* interstitial lung disease; *JIA,* juvenile idiopathic arthritis; *JDM,* juvenile dermatomyositis; *MCTD,* mixed connective tissue disease; *MPA,* microscopic polyangiitis; *SLE,* systemic lupus erythematosus; *SSc,* scleroderma.

# Juvenile Idiopathic Arthritis

## Epidemiology

JIA is the most common chronic rheumatic disease in childhood, with a prevalence of 16–150 per 100,000.[2] The term JIA includes a heterogeneous group of diseases that have in common the following characteristics: arthritis, which begins before the age of 16 years, persists for at least 6 weeks, and for which no specific cause can be found. Overall, girls are affected approximately twice as commonly as boys are, but this varies considerably with the different subtypes. The age of onset ranges from less than 1 year to 16 years, with a peak between 1 and 3 years for the most common subtypes. The onset of JIA in the first 6 months of life is rare and should raise suspicion of another diagnosis. In a large multiethnic cohort of JIA patients, children of European descent had an increased risk of JIA, and there were significant differences in the frequency of different subtypes of JIA in different ethnic groups.[3]

## Etiology and Pathogenesis

The cause of JIA remains unknown, and the pathogenesis has not been clearly elucidated. Given the heterogeneity of the disease phenotypes, it is not surprising that the different subtypes have different genetic predispositions and associations, different autoantibody profiles, and differences in immune dysregulation. JIA is a complex genetic disease, where there are multiple genetic associations. HLA-A2 is associated with early-onset JIA, especially in the oligoarticular subtype. There are strong HLA associations with oligoarticular JIA (HLA-DRB1*08, 11, and 13 and DPB1*02). HLA DRB1*08 is also associated with rheumatoid factor negative polyarticular JIA), and RF-positive JIA is associated with DRB1*04, DQA1*03, and DQB1*03.[4] There is also a significant association of HLA-B27 with enthesitis-related arthritis (ERA) and juvenile ankylosing spondylitis.[5] A number of polymorphisms have been associated with JIA, including a polymorphism involving the protein tyrosine phosphatase N22 gene (PTPN22).[6] Antinuclear antibodies are frequently found in children with oligoarticular disease and somewhat less frequently seen in polyarticular JIA. The presence of ANA is clearly associated with a higher risk of uveitis, the most common extraarticular manifestation of both oligoarthritis (occurring in 21%) and RF-negative polyarticular arthritis (14%).[7] The systemic subtype is characterized by a lack of autoantibodies and by dysregulation of interleukin-1β production and significant elevations of interleukin-6 (IL-6). Studies using biologic agents that block the actions of IL-6 (tocilizumab) and IL-1β (anakinra, canakinamab, and rilonacept) have proven to be effective in treating patients with active systemic disease. The dysregulation of IL-1β in systemic JIA and the efficacy of IL-1β inhibitors in reversing manifestations of the disease suggest that it is more likely an autoinflammatory disease than an autoimmune disease.

## Clinical Manifestations

The clinical manifestations of JIA depend on the subtype, which is defined by the presenting features within the first 6 months of disease onset (Table 58.3). The most common subtype in Europe and North America is oligoarticular JIA, which primarily affects large joints. This can remain oligoarticular or extend after the first 6 months to involve additional joints. Both oligoarticular and RF-negative polyarticular JIA most commonly affect young preschool age girls. Asymptomatic anterior uveitis occurs in oligoarticular JIA, RF-negative polyarticular JIA, and psoriatic arthritis. If undetected by routine slit lamp examination, uveitis can result in blindness. Rheumatoid factor-positive polyarticular JIA most commonly first manifests in older girls, is phenotypically similar to adult rheumatoid arthritis, where arthritis affects small and large joints in a symmetrical pattern, and is sometimes associated with rheumatoid nodules. ERA typically develops in boys over the age of 8 years and is characterized by predominantly lower limb arthritis in association with enthesitis, inflammation where ligaments, tendons, or joint capsules attach to bone. This may be the forerunner of ankylosing spondylitis in adult life. The heel and knee are the most commonly involved entheses. ERA may be accompanied by symptomatic anterior uveitis with a painful, red eye in a proportion of patients. Arthritis may occur at disease onset but sometimes only develops after weeks or even months. The diagnosis of psoriatic arthritis in children may depend on arthritis associated with psoriatic nail changes, dactylitis, or a family history of psoriasis, since arthritis frequently precedes the development of psoriatic skin lesions by many years. Systemic arthritis is distinct from the other subtypes, both clinically and biologically, since the systemic manifestations of fever, rash, hepatosplenomegaly, lymphadenopathy, and serositis (particularly pericarditis) are usually prominent at onset, and it is thought to have an autoinflammatory pathobiology.

## Table 58.3

## Subtypes of Juvenile Idiopathic Arthritis

| Subtype | Subtype Inclusion Criteria (9) | % of All JIA (2) | Sex Ratio (2) |
|---|---|---|---|
| Systemic | Arthritis PLUS fever for 2 weeks, daily for at least 3 days PLUS at least one of the following:<br>■ Rash<br>■ Serositis<br>■ Generalized lymphadenopathy<br>■ Hepatomegaly or splenomegaly | 4%–17% | F=M |
| Oligoarticular | 4 or fewer affected joints within first 6 months<br>Persistent—remain with ≤ four joints<br>Extended—>four joints after 6 months | 27%–56% | F≫>M |
| Polyarticular RF negative | ≥Five joints in first 6 months | 11%–28% | F≫M |
| Polyarticular RF positive | ≥Five joints in first 6 months | 2%–7% | |
| Enthesitis related arthritis | Arthritis PLUS enthesitis OR<br>Arthritis OR enthesitis PLUS at least 2 of the following:<br>■ Sacroiliac joint tenderness and/or inflammatory spinal pain<br>■ Presence of HLA-B27<br>■ Family history of HLA-B27-associated disease<br>■ Anterior uveitis (usually symptomatic)<br>■ Onset of arthritis in a boy > 8 years | 3%–11% | M≫F |
| Psoriatic arthritis | Arthritis PLUS Psoriasis OR<br>Arthritis PLUS at least 2 of:<br>■ Dactylitis<br>■ Nail pitting or onycholysis<br>■ Psoriasis in a first-degree relative | 2%–11% | F>M |
| Unclassified | Does not meet criteria for one of above OR<br>Meets criteria for >1 of above | 11%–21% | |

*JIA*, Juvenile idiopathic arthritis.

Macrophage activation syndrome (MAS) is a severe, potentially life-threatening complication of JIA, occurring in approximately 10% of children with the systemic subtype. Characteristic clinical features are sustained, high fever, hepatosplenomegaly, lymphadenopathy, and sometimes bleeding, bruising, and encephalopathy. Characteristic laboratory features include a sudden drop in white blood cell count, platelet count, and hemoglobin, with elevated transaminases, LDH, coagulopathy, and very high levels of serum ferritin. Dysregulation of the IL-1β pathway is prominent in both sJIA and MAS. The mortality in a recent large series of patients with systemic JIA and MAS was 8%.[8]

## Classification and Diagnosis of Juvenile Idiopathic Arthritis

The International League of Associations for Rheumatology (ILAR) criteria for the classification are widely accepted. The inclusion criteria for the different subtypes are listed in Table 58.3. There are also a number of exclusions for each category[9] that are beyond the scope of this chapter.

## Pulmonary Involvement in Juvenile Idiopathic Arthritis

Pulmonary involvement in JIA is uncommon and significant pulmonary manifestations, except for pleuritis, are sufficiently rare that these warrant thorough evaluation for other conditions such as infections, systemic vasculitis, SLE, and other connective tissue diseases. Pleuritis is a well-reported manifestation of systemic JIA, but it is usually accompanied by pericarditis. One should be particularly careful to exclude the diagnosis of SLE in an older girl who presents with isolated pleuritis and arthritis. There are few reports of pulmonary disease in JIA. One of the earliest studies completed more than 30 years ago found pulmonary disease in 4% of JIA patients. The radiological abnormalities included pneumonitis, interstitial reticular and nodular infiltrates, and pleural effusions. Pathologic correlates of these findings were pulmonary hemosiderosis, lymphoid follicular bronchiolitis, and LIP. Some patients with parenchymal disease developed radiographic evidence of interstitial fibrosis.[10] There are additional reports of pulmonary hemosiderosis in JIA[11,12] and a report of LIP that actually preceded the diagnosis of RF-positive JIA by 10 years.[13] Recently patients with familial JIA-like symptoms and ILD have been described with COPA (coatomer subunit $\alpha$) gene mutations, which impair vesicular transport and cause endoplasmic reticulum stress.[14] It is possible that some of the extreme phenotypes of lung disease in association with JIA are also inherited monogenic inflammatory diseases that we will discover as our knowledge increases and with improved genetic testing.

Severe pulmonary manifestations, seen predominantly with systemic JIA, are uncommon but may be associated with a high mortality rate. An international series described 25 patients with systemic JIA and PAH ($n = 16$), ILD ($n = 7$), and/or alveolar proteinosis (AP; $n = 5$), with six patients having more than one diagnosis.[15] In comparison to a large cohort of systemic JIA patients in a North American registry, these patients were more likely to be female and to have active systemic disease features, and were more likely to have been treated with biological agents, most commonly IL-1 inhibitors, which were used in two-thirds of patients. There was a striking association of these pulmonary complications with MAS, which was reported in 60% of patients at the time of the pulmonary diagnosis, approximately 6 times the rate at which MAS is reported to occur at any time during the disease course. Symptoms most commonly reported were shortness of breath, exertional dyspnea, cough, and chest pain, but some patients only had digital clubbing. Most concerning is that 17 patients died within a mean period of less than 9 months from the time of the pulmonary disease diagnosis. Since almost all patients developed severe pulmonary complications in the biological era (after the year 2000), biological agents have neither prevented nor effectively treated these complications. Further surveillance studies will help determine whether biological agents may potentially be involved in their pathogenesis.

One systemic JIA patient with PAH in the absence of documented pulmonary parenchymal disease responded well to treatment with cyclosporine and systemic corticosteroids.[16] A 5-year-old girl who developed radiographic features suggestive of progressive pulmonary fibrosis had interstitial and intraalveolar cholesterol granulomas identified on lung biopsy. Although she appeared to stabilize on immunosuppressive treatment with methotrexate and etanercept, she subsequently succumbed with respiratory failure.[17] We have seen an additional systemic JIA patient with a similarly refractory disease course who developed fatal pulmonary lipoid pneumonia (Fig. 58.1). A 21-year-old male, following a long history of severe systemic JIA with persistent systemic symptoms and damaging arthritis, developed endogenous lipoid pneumonia that was ultimately treated with double lung transplantation.[18]

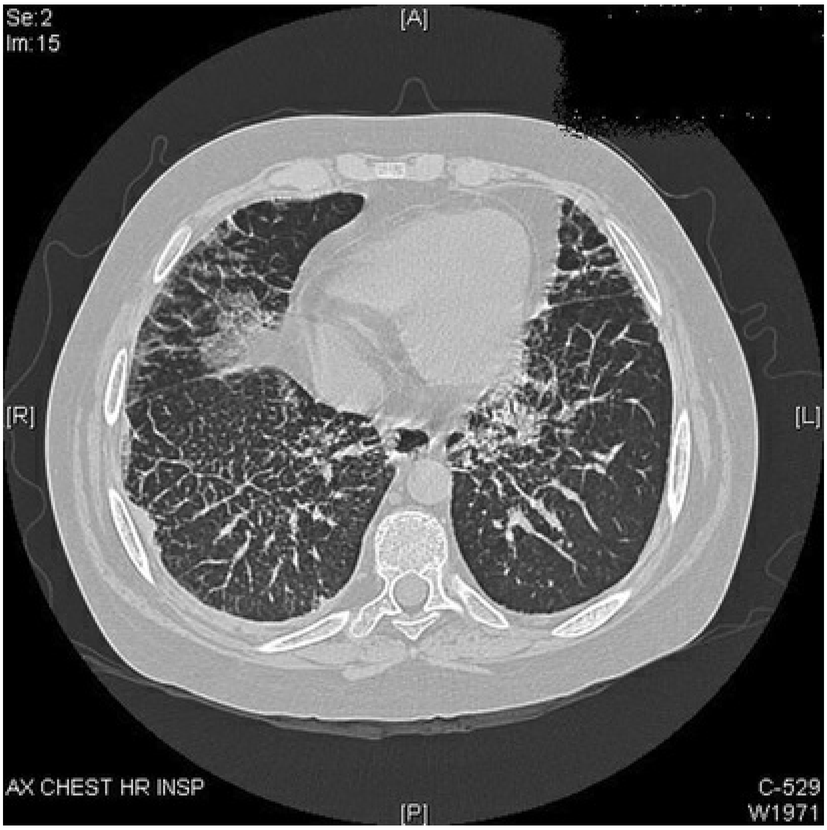

**FIG. 58.1** Twelve-year-old child with systemic onset juvenile idiopathic arthritis at age 15 months who developed gradual onset of dyspnea, cough, and crackles on auscultation. High-resolution computed tomography scan showed bilateral diffuse interstitial changes, including thickening of the interlobular septa, nodules, and areas of fibrosis and ground glass densities. A lung biopsy confirmed the diagnosis of endogenous lipoid pneumonia with interstitial and

intraalveolar cholesterol granulomas.

Pulmonary manifestations of MAS include lung infiltrates, pneumonitis, pulmonary hemorrhage, and pulmonary edema, which may result from myocardial dysfunction associated with the hypercytokinemia typical of MAS. One large series reported pulmonary involvement in 50% of patients, and one-third of all patients required ventilatory support.[19]

BOOP has been described in adults with rheumatoid arthritis,[20] but there are few reports of this complication associated with JIA.[21] BO was described in a 12-year-old girl following treatment of her arthritis with intramuscular gold injections. Despite immunosuppressive treatment and subsequent lung transplantation, the BO was progressive and fatal.[22] BO has also been reported in a patient with JIA whose first symptoms were those related to pneumomediastinum.[23]

Studies of pulmonary function in JIA have detected abnormal pulmonary function tests (PFTs) in more than 50% of asymptomatic patients. Restrictive disease patterns have been more commonly identified than obstructive abnormalities.[24] Results of diffusing capacity of the lungs for carbon monoxide (DLCO) measurements have been more variable with reductions in DLCO reported in 3.7%–45%.[25–27] Reductions of maximum inspiratory and expiratory pressures, suggestive of respiratory muscle weakness, may influence PFTs in these patients, but there may also be a correlation of impaired pulmonary function with disease severity, as measured by the erythrocyte sedimentation rate (ESR) and requirement for treatment with methotrexate. Since methotrexate is the most commonly used second-line drug for the treatment of JIA, it is important to consider whether it has any impact on the development of lung disease. Low-dose weekly methotrexate has been reported to cause an acute pneumonitis associated with fever, cough, and dyspnea. There have also been concerns raised about methotrexate-induced chronic, progressive pulmonary fibrosis.[28,29] However, several studies suggest that methotrexate does not increase the risk of pulmonary disease in children with arthritis.[25,30,31]

## Treatment

Nonsteroidal antiinflammatory drugs (NSAIDs) and intraarticular corticosteroid injections[32] are considered first-line treatments for children with JIA and may be all that is required to treat oligoarticular involvement or mild disease. Children whose arthritis does not respond adequately, especially those with a polyarticular course, are treated with low-dose weekly methotrexate. The advent of biological agents has dramatically improved outcomes for children whose arthritis is refractory to methotrexate.[33] Tumor necrosis factor alpha (TNF$\alpha$) inhibitors, such as etanercept,[34] adalimumab,[35] or infliximab, are usually used if there is an inadequate response to methotrexate or if there is intolerance to methotrexate. Newer biological options for polyarticular course JIA include abatacept[36] and tocilizumab.[37] There are different treatment algorithms followed for different subtypes: neither methotrexate nor TNF$\alpha$ inhibitors are particularly effective for systemic JIA. Children who have persistent systemic symptoms and arthritis despite NSAIDs usually respond to systemic corticosteroids. IL-1 antagonists such as anakinra,[38] canakinumab,[39] and rilonacept[40] or the IL-6 antagonist, tocilizumab,[41,42] have proven to be highly efficacious for steroid-dependent systemic JIA. Pediatric rheumatologists are changing the treatment paradigm to treat earlier and more aggressively to try to change the course of the immune response and prevent long-term joint damage in all subtypes of JIA. For example, many treat JIA patients with IL-1 inhibition, even before corticosteroids are used. Acute symptomatic serositis, especially pericarditis, may require intravenous pulsed methylprednisolone. A similar approach is taken for MAS with early use of cyclosporine or IL-1 inhibitors if there is not a rapid response. ERA does not respond as well as other subtypes to methotrexate but may respond to treatment with sulfasalazine.[43] Axial spine involvement may need early institution of TNF$\alpha$ inhibitors.

## Prognosis

The mortality in JIA is well below 1%,[44] with a disproportionately higher mortality risk in the systemic subtype, largely because of

MAS associated with the disease and infections associated with immunosuppressive therapy. Overall, active arthritis persists on long-term follow-up, even into adult life, in more than 50% of patients. Poor prognostic features of the systemic subtype include persistent systemic symptoms, marked thrombocytosis, and polyarticular arthritis in the first 6 months of disease.[45] For the other subtypes, positive rheumatoid factor, marked and persistent elevation of inflammatory markers, involvement of the hip joint, and early joint space loss and erosions predict poor outcome.[46,47] Acute pleuritis usually responds well to treatment without sequelae, but the pulmonary manifestations such as PAH, ILD, and AP carry a high mortality.

# Systemic Lupus Erythematosus

## Epidemiology

SLE predominantly affects young women, but in approximately 15%–20% of individuals, the disease presents prior to the age of 18 years. SLE is relatively rare in children, with an estimated incidence of 10–20 per 100,000 that is considerably higher in black, Hispanic, South and South-East Asian, as well as North American First Nations populations. In postpubertal adolescents, females are clearly more commonly affected than males (~6 : 1), but in the younger age groups, the female predominance is much less marked.[48]

## Pathogenesis

SLE is the prototypic autoimmune disease, characterized by presence of autoantibodies in virtually all patients. There is substantial evidence of both innate and adaptive immune dysregulation and of immune activation and autoimmunity, resulting from the interaction of lupus-associated genes with environmental triggers. Environmental triggers include ultraviolet radiation, infections, drugs, and chemicals. The activation of the immune system is amplified by lupus autoantibodies and their associated nucleic acids, together with cytokines and chemokines, resulting in inflammation and tissue damage.[49] Autoantibodies can actually be detected many years before the development of clinically symptomatic SLE.[50]

## Clinical Features

Common presenting symptoms of SLE in children are rash, joint pain, and constitutional symptoms such as fatigue, fever, and weight loss. The most common presenting features in a large cohort of pediatric lupus patients were arthritis (67%), malar rash (66%), nephritis (55%), and central nervous system disease (27%).[51]

The American College of Rheumatology criteria for the classification of lupus in adults appear to apply well to children with SLE (Box 58.1) and have been reported to achieve a sensitivity of 96% and specificity of 100% for the diagnosis of SLE in a pediatric population.[52] Although the classification criteria require that four or more of the 11 criteria are present, there are no published diagnostic criteria, and the diagnosis of SLE in children can certainly be made when fewer than four criteria are present.

**Box 58.1**

### Classification Criteria for Systemic Lupus Erythematosus

1. Malar rash
2. Discoid rash
3. Photosensitivity
4. Nasal or oral ulcers
5. Arthritis involving at least two joints
6. Serositis
    Pleuritis, or
    Pericarditis
7. Renal disorder
    Proteinuria >0.5 g/day, or
    Cellular casts in the urine
8. Neurologic disorder

    Seizures, or
    Psychosis
9. Hematologic disorder
    Hemolytic anemia, or
    Leukopenia (<4000/mm), or
    Lymphopenia (<1500/mm), or
    Thrombocytopenia (<100,000/mm)
10. Immunologic disorder
    Anti-DNA antibody, or
    Anti-Sm antibody, or
    Antiphospholipid antibody
11. Positive antinuclear antibody

A person is classified as having SLE if at least 4 of the 11 criteria are present serially or simultaneously.

*SLE,* Systemic lupus erythematosus.

Modified from Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum*. 1997;40(9):1725.

## Pulmonary Involvement

Pulmonary involvement in pediatric SLE has been reported to occur in 18%–40% of patients within the first year of diagnosis and in 18%–81% of patients at any time during the disease course.[53] It occurs more frequently in Afro-Caribbeans.[54] Studies that report higher rates of pulmonary involvement include abnormal pulmonary function tests or abnormal imaging studies, even in the absence of symptoms. Pulmonary involvement can indeed be very mild, or even asymptomatic, but can also be life-threatening with respiratory failure. Pulmonary lupus has been reported to be more severe when SLE begins within the first 2 years of life.[55] Pleuritis with pleural effusion is the only pulmonary manifestation to be included among the criteria for the classification of SLE[56] and occurs in 9%–32% of patients,[57–59] and may even be the initial clinical manifestation of SLE. In a large cohort of adult lupus patients, pleuritis was found to occur more frequently in patients with a younger age at disease onset, and longer disease duration, who manifested more cumulative disease-related damage, and in those who had positive anti-Sm and anti-RNP antibodies.[60] Pleural effusions are exudative and may be unilateral or bilateral. These must be differentiated from infectious exudative effusions and from transudative effusions related to renal or cardiac disease. SLE is associated with an increased risk of a wide range of infections, including bacterial, viral, mycobacterial, fungal, and parasitic infections, with the respiratory tract as one of the common sites.[61] In addition, immunosuppressive treatments to control the disease confer an increased risk of opportunistic infections such as pneumocystis, cytomegalovirus, and fungal infections. Inflammatory pulmonary lesions may be difficult or even impossible to differentiate from pulmonary hemorrhage or pulmonary infections. Since infection is the leading cause of death in children with lupus,[62] rigorous exclusion of potential infections is necessary before attributing pulmonary manifestations to disease activity. Cultures of sputum (if obtainable), nasopharyngeal secretions, blood, and pleural fluid should be performed, but bronchoalveolar lavage (BAL) and lung biopsy may be necessary. Children at risk should be carefully evaluated for tuberculosis.

Acute pneumonitis is uncommon in adults with lupus and even less common in pediatric lupus. The presentation includes fever, nonproductive cough, dyspnea, pleuritic chest pain, and tachypnea. Chest radiographic findings are nonspecific, with infiltrates that can mimic infections or hemorrhage and that may be accompanied by pleural effusions (Fig. 58.2). Chronic ILD due to SLE is extremely rare; in a necropsy series of 90 lupus patients, none had acute or chronic pneumonitis.[63] If chronic pneumonitis does occur, Sjögren syndrome (SS), infection, or drug toxicity should be excluded. Chronic ILD can follow acute lupus pneumonitis[64] but can also develop in a more insidious manner with exertional dyspnea, chronic cough, pleuritic chest pain, and basal rales.[65] Patients tend to have multisystem manifestations of SLE. Pulmonary function studies typically follow a slowly progressive course with a restrictive pattern, but may improve or at least stabilize. Histopathology demonstrates alveolar wall thickening, interstitial fibrosis, interstitial lymphocytic infiltrates, and granular deposits of immunoglobulin and complement.

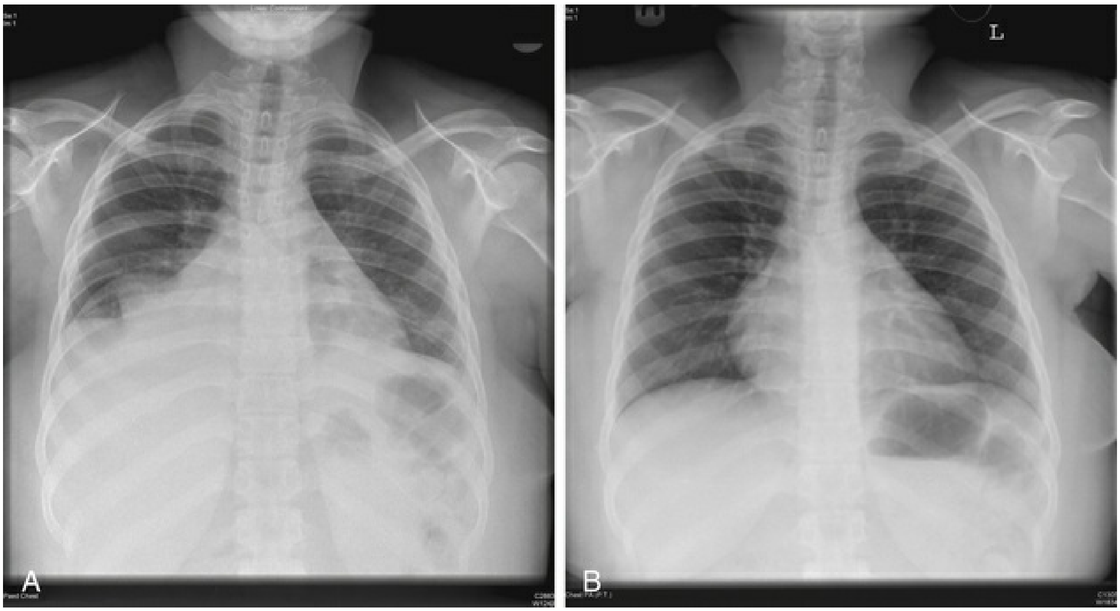

**FIG. 58.2** (A and B) Chest radiographs of a 10-year-old girl diagnosed with systemic lupus erythematosus who presented with acute onset of fever, dyspnea, chest pain, malaise, weight loss, malar skin rash, and arthralgias. (A) Initial presentation with pleuritis and acute interstitial pneumonia. Radiograph shows bilateral pleural effusions and lower lobe opacification, worse on right side. (B) Rapid resolution of symptoms and imaging abnormalities after pulse steroid therapy.

Pulmonary hemorrhage is a rare but potentially life-threatening complication of SLE in children that has been reported to occur at disease onset[66] or during the course of the disease. Significant acute pulmonary hemorrhage is accompanied by severe dyspnea with or without hemoptysis and a sudden drop in hemoglobin, and it may progress rapidly to respiratory failure. Lupus nephritis is present in a high proportion of patients. The mortality resulting from pulmonary hemorrhage in adult series of SLE has been as high as 50%,[67] and one report suggests an even higher mortality in childhood lupus.[68] Chest radiographs show diffuse alveolar opacities indistinguishable from fluid or infection. Lupus patients with acute pulmonary hemorrhage should be carefully investigated for pulmonary infections. In one report,[69] more than 50% of patients had an infection identified within 48 hours of presentation with pulmonary hemorrhage. Infections identified included pseudomonas, cytomegalovirus, and aspergillus. Empiric treatment with antibiotics may improve survival. Thrombotic thrombocytopenic purpura should be ruled out, particularly in the presence of fever, thrombocytopenia, and renal dysfunction, since this may be associated with SLE.

Pulmonary hypertension is rare in children with SLE, but has been reported in 14% of adult patients, followed at a tertiary care center.[70] In a large series of adult patients followed at nontertiary care centers, the prevalence of pulmonary hypertension determined by echocardiography was found to be 4.2%.[71] The presence of a lupus anticoagulant was the only risk factor identified for the development of pulmonary hypertension in this cohort. Raynaud phenomenon occurs more frequently in lupus patients with pulmonary hypertension than in other lupus patients. Potential causes of pulmonary hypertension in SLE include pulmonary vasculitis, pulmonary thromboembolism, ILD, and valvular heart disease. Serum endothelin levels have been found to be higher in patients with pulmonary hypertension than in other lupus patients, and antiendothelial cell antibodies are elevated in patients with active lupus and pulmonary hypertension.[72]

Antiphosphopholipid antibodies are found more frequently in SLE than other connective tissue diseases, with a prevalence of 44% for anticardiolipin antibodies, 40% for anti-β2 glycoprotein I, and 22% for the lupus anticoagulant.[73] Anticardiolipin titers correlate with lupus disease activity. Several studies have confirmed a strong association with antiphospholipid antibodies and vascular thromboses in children with SLE. Lupus anticoagulant appears to confer the highest risk of thrombosis, but there is also a clear association of thrombosis with anticardiolipin and anti-β2GPI,[74,75] Pulmonary embolism is the most frequent pulmonary manifestations of the antiphospholipid antibody syndrome, and recurrent pulmonary embolism can result in pulmonary hypertension.[76]

Shrinking lung syndrome occurs predominantly in adults with SLE but has also been reported in children. It typically presents with progressive dyspnea, pleuritic chest pain, and tachypnea. Chest radiographs may demonstrate reduced lung volumes, raised hemidiaphragms, and basal atelectasis (Fig. 58.3); PFTs are usually restrictive. Chest computed tomography (CT) scans do not reveal significant pleural or parenchymal lung disease. The cause of this syndrome in SLE remains unclear, but diaphragmatic dysfunction with poor diaphragmatic movement demonstrable on fluoroscopy has been reported in some pediatric cases.[77] Diaphragmatic dysfunction with subsequent shrinking lung syndrome has been linked to symptomatic pleuritis.[78] Although the optimum treatment is not clear, some patients appear to respond to immunosuppressive therapy.[79]

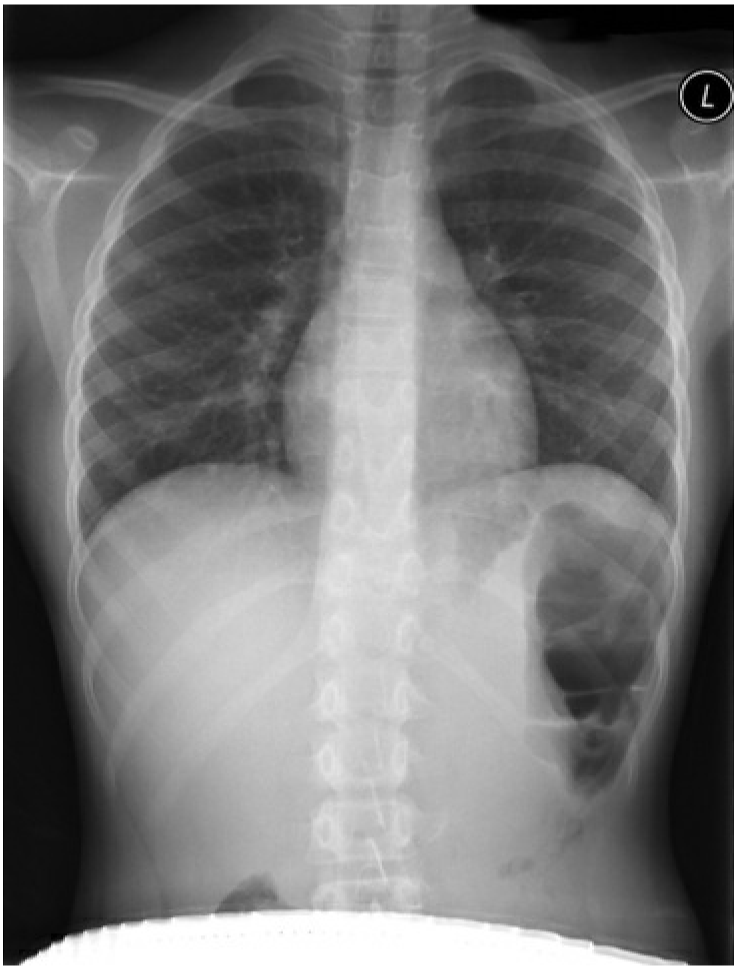

**FIG. 58.3** Chest radiograph of an 11-year-old child diagnosed with lupus and "shrinking lung syndrome." Child presented with fever, muscle weakness, weight loss, malaise, and severely restricted pulmonary function tests. Chest radiograph showed an elevated left hemidiaphragm while high-resolution computed tomography scan showed only subtle nonspecific changes out of keeping with pulmonary function. Pulmonary function tests normalized over a period of 6 months with high-dose prednisone treatment.

Studies in pediatric SLE patients without clinically or radiographically apparent lung disease have found PFT abnormalities in at least one-third, with a range of 38%–84%.[80] PFT abnormalities most frequently seen are restrictive with or without a diffusion abnormality. Most studies have not shown any correlation between PFT abnormalities and lupus disease activity. It is important to note that isolated abnormal pulmonary function tests in children with lupus do not predict progressive lung disease.[81]

High-resolution CT imaging in a cohort of 60 Norwegian patients with childhood-onset SLE revealed that 8% had abnormal findings, including micronodules and bronchiectasis, but none had ILD.[82] These findings did not correlate with PFT abnormalities, but a more recent study did show some correlations.[83] Although CT imaging is more sensitive than plain chest radiography, routine screening of asymptomatic pediatric lupus patients with CT is not recommended.

## Treatment

Since infection is the major cause of mortality in pediatric SLE, children with pulmonary manifestations require rigorous investigation and treatment of infectious complications. It is also important to exclude other causes of pulmonary pathology in SLE, such as thromboembolism, drug toxicity, and the impact of cardiac or renal disease. Corticosteroids are highly effective in treating lupus pleuritis and pleural effusions, and remain the mainstay of treatment for moderate to severe pulmonary manifestations of SLE in children. The majority of children with SLE are treated with hydroxychloroquine, which is particularly effective for cutaneous disease, arthritis, and mild constitutional symptoms, and in reducing the risk of disease flares.[84] Immunosuppressive drugs such as azathioprine[85] and mycophenolate mofetil[86] are frequently used to prevent organ damage and as corticosteroid-sparing agents. There may also be a role for methotrexate[87] and cyclosporine.[88] For the most severe manifestations such as pulmonary hemorrhage, pulse methylprednisolone (30 mg/kg per dose up to 1000 mg) may be administered daily for 3 days or longer, followed by high-dose daily oral systemic corticosteroids. Although there are no controlled clinical trials for the treatment of pulmonary hemorrhage, intravenous pulse cyclophosphamide (CYC) is frequently used[89] and appears to be associated with improved survival.[90] Although plasmapheresis is not of proven benefit, it has been used in life-threatening pulmonary hemorrhage. Certainly, in patients with TTP and catastrophic antiphospholipid antibody syndrome, plasmapheresis can be a life-saving therapy.[91] Rituximab, a B-cell depleting biologic agent, is assuming an increasing role in the treatment of pediatric SLE, but its role in the treatment of pulmonary manifestations remains to be defined.[92,93] Vascular thromboses associated with antiphospholipid antibodies require anticoagulation.

## Prognosis

Disease severity is greater in children with SLE than in adults, and the majority of children develop organ damage within 5–10 years of diagnosis. Long-term morbidity includes premature atherosclerosis and osteoporosis.[48] Five-year survival rates in pediatric SLE range from 85% to 95%, but this may be improving, with a recent study reporting a 99.6% survival rate. Renal disease and infections were the most common causes of death.[44]

# Juvenile Dermatomyositis

JDM is a rare autoimmune inflammatory myositis in which a capillary vasculopathy causes characteristic cutaneous and muscle manifestations, although other organs can be affected. In children, symptomatic lung involvement is infrequent, which is distinct from adult dermatomyositis (DM), where symptomatic lung involvement occurs in more than half of patients.

## Epidemiology

JDM is the most common inflammatory myopathy in children, accounting for approximately 85% of cases[94] and has an incidence of 0.2–0.4 per 100,000 children.[95–98] It is a distinct disease entity from adult DM. Peak incidence occurs from 5 to 10 years of age,[97,98] and females are 2 to 5 times more likely to develop the disease than males.[96,98,99] A case report in monozygotic twins has suggested a genetic predisposition to JDM in some families.[100]

## Pathogenesis

Although the etiology of JDM is unknown, genetics, environmental exposure, and infections are thought to be related to the disease development.[94,101] No specific causative gene has been found, but certain HLA alleles (HLA-B8, HLA-DQA1*0301, and HLA-DQA1*0501) and polymorphisms in tumor necrosis factor-alpha and interleukin-1 receptor antagonist have been reported as risk factors for the development of JDM and for certain phenotypes.[102,103] There is increased type I interferon gene expression[104] and upregulation of MHC class I expression on the surface of muscle fibers. JDM is characterized by various degrees of vasculopathy with immune complex deposition and the development of calcinosis in the later stages of disease.

## Clinical Manifestations

JDM has a relatively homogeneous presentation in children with mainly cutaneous and muscle manifestations.[99,105] The initial symptoms are usually skin rash (often with heliotrope rash over the eyelids and Gottron's papules over extensor surfaces of joints), fever, and proximal muscle weakness. Characteristic changes in the nail fold capillary bed are common, and measuring the density of capillaries/mm may be a useful tool for monitoring clinical activity in JDM.[106,107] Other disease manifestations include skin ulcerations, soft tissue calcification, arthritis, lipodystrophy, and insulin resistance. Serious gastrointestinal and lung involvement occur only occasionally.

## Diagnosis

According to the traditional criteria of Bohan and Peter,[108,109] the diagnosis of JDM is based on the following five criteria: proximal muscle weakness, characteristic rash, elevated muscle enzymes, characteristic myopathic findings on electromyography, and typical muscle biopsy findings. Criteria for definite JDM are the pathognomonic rash and three other criteria, while the diagnosis of probable JDM requires the rash and two other criteria.[105] Most children with JDM do have both proximal muscle weakness and rash, and elevated serum muscle enzymes are usually, but not always, present. Newer proposed criteria include the presence of nail fold capillary abnormalities,[106] magnetic resonance imaging that demonstrates the presence of muscle inflammation,[110] calcinosis, and dysphonia.[111] In cases where the diagnosis remains uncertain, the more invasive muscle biopsy may be necessary. JDM must be differentiated from other noninflammatory causes of muscle weakness (muscular dystrophies and metabolic myopathies), transient postviral myositis, and myositis due to other rheumatologic diseases (systemic scleroderma, SLE, MCTD, and systemic JIA). Elevated C-reactive protein and erythrocyte sedimentation rate and the presence of antinuclear antibodies are common but nonspecific findings that have limited diagnostic value. Myositis-specific antibodies, which are commonly associated with adult forms of DM and polymyositis, are uncommon in JDM; hence they are not usually helpful in making the diagnosis.[112,113] However, the presence of anti-Jo-1 and antisynthetase antibodies are associated with ILD in adults[114] and may also be associated with more severe disease in children that more closely resembles adult DM.[102,112]

## Pulmonary Involvement

ILD is a common cause of morbidity and mortality for adult onset DM and polymyositis, occurring in up to 65% of cases.[115] In adults, ILD may precede, appear concomitantly with, or develop after the onset of skin and muscle manifestations.[115] In contrast, symptomatic pulmonary involvement is infrequent in children with JDM. In the largest case series of JDM presented to date, only 1 of 105 patients (<1%) at the Hospital for Sick Children in Toronto, Canada, developed symptomatic ILD (Fig. 58.4).[105] Other case series have reported higher rates of ILD detected by pulmonary function testing and HRCT scanning; however, most of these cases were not histologically confirmed.[116,117] Although symptomatic ILD is rare enough that its description is mainly limited to case reports,[118–121] it is important to recognize its onset, as it can be rapidly progressive and fatal (Fig. 58.5).[119–121] A Japanese nationwide collaborative study identified 10 cases of rapidly progressive interstitial lung disease (RP-ILD), seven of whom died.[122] Antimelanoma differentiation-associated gene 5 (MDA5) antibodies, and high serum levels of interleukin 18 (Il-18), Krebs von den Lungen-6 (KL-6), and ferritin were associated with RP-ILD.[122] Pneumomediastinum is a characteristic complication of adult DM with interstitial pneumonitis[123] and has also been reported in JDM (Fig. 58.6).[118–121] Aspiration pneumonia and hypoventilation are also frequently reported pulmonary complications in adult DM.[115] In adult studies, the strongest predictive factor for ILD in patients with myositis is the presence of anti-Jo-1 antibodies.[114]

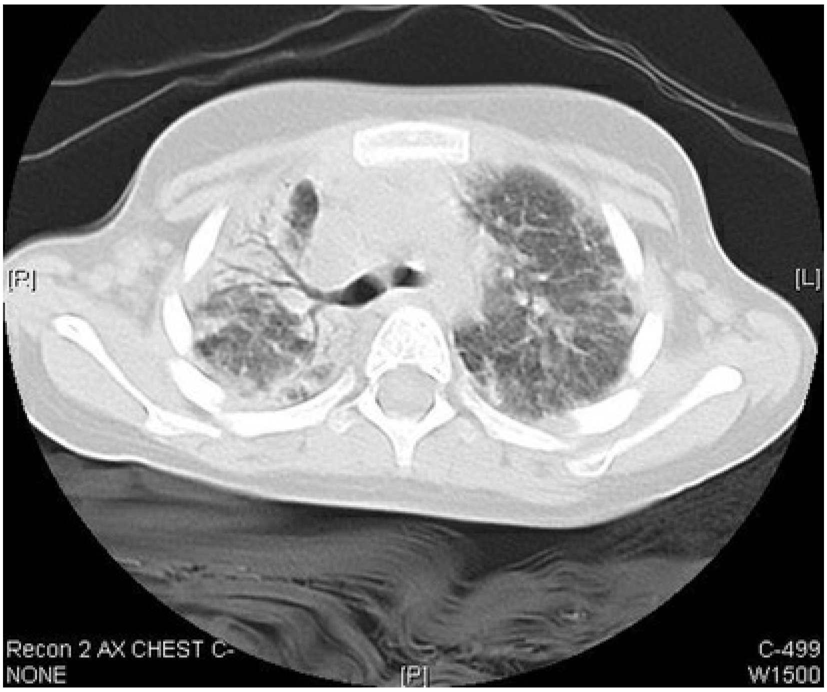

**FIG. 58.4** Two-year-old who presented with fever, hypoxia, and persistent chest infiltrates. High-resolution computed tomography showed bilateral patchy airspace consolidation with air bronchograms. A lung biopsy confirmed the diagnosis of bronchiolitis obliterans organizing pneumonia. Six months later the child developed myalgias and heliotrope rash and was diagnosed with juvenile dermatomyositis.

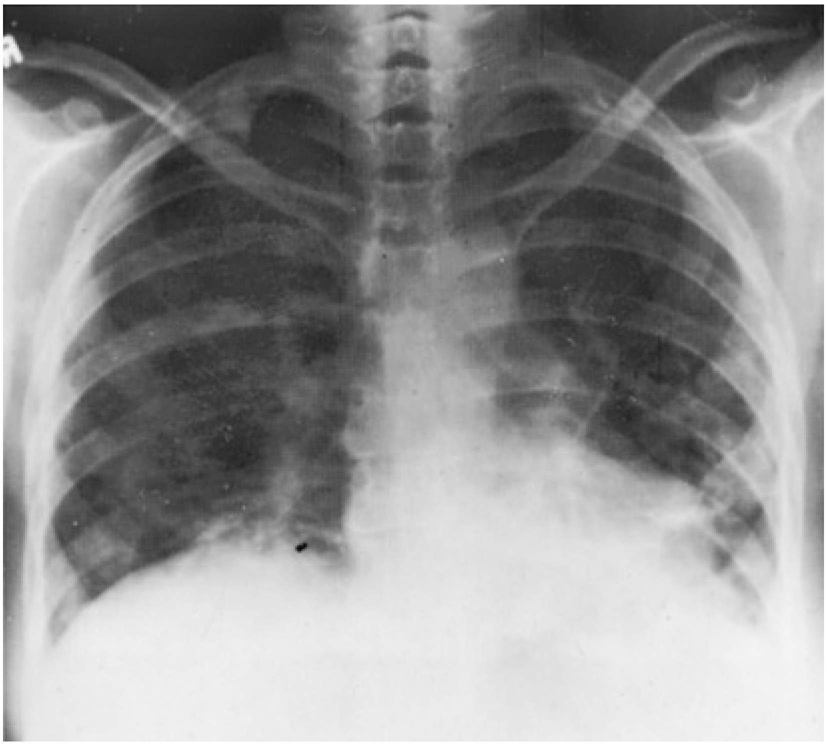

**FIG. 58.5** Chest radiograph of a 21-year-old female diagnosed with juvenile dermatomyositis at 12 years of age and onset of slowly progressive pulmonary fibrosis at 18 years of age. The heart is normal in size, and soft tissue calcifications are present in both axillae. Interstitial thickening and cystic changes are bilateral and most pronounced at the bases.

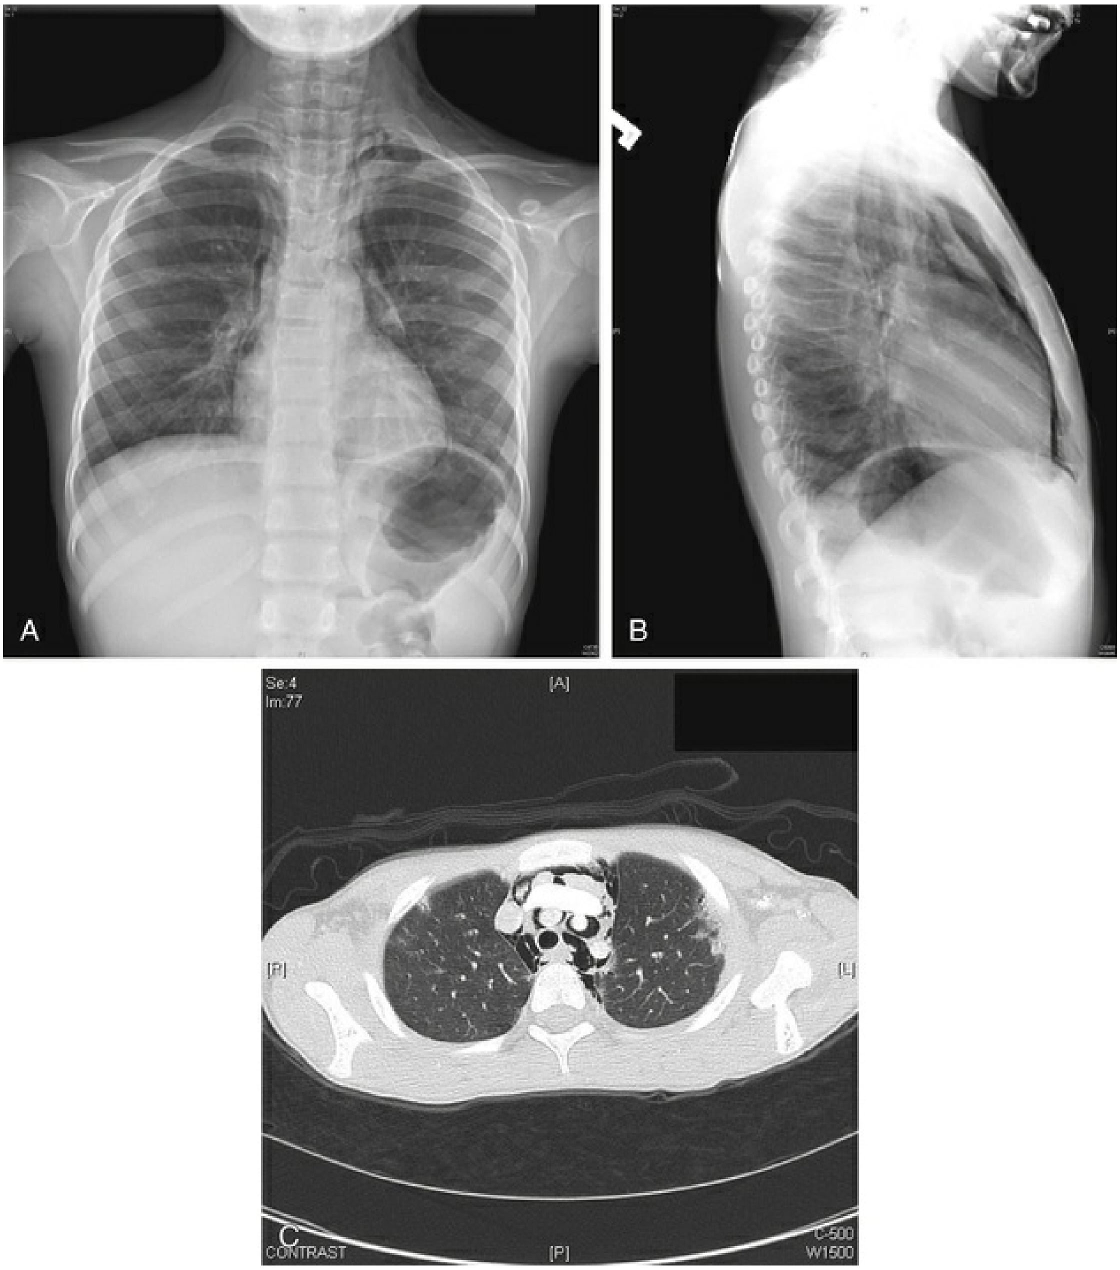

**FIG. 58.6** (A) Posterior-anterior (PA) and (B) lateral view of chest radiograph of 9-year-old child presenting with juvenile dermatomyositis showing extensive pneumomediastinum and blunting of right costophrenic (CP) angle. (C) High-resolution computed tomography scan of chest also shows multiple pleural-based wedge-shaped opacities with interstitial thickening and cystic areas consistent with early interstitial lung disease (usually NSIP pattern).

The most common presenting symptoms of ILD are cough and dyspnea, although ILD has been reported to occur without symptoms. Pulmonary function tests show a restrictive ventilation defect, with decreased lung volumes, reduced diffusing capacity for carbon monoxide and normal or elevated $FEV_1$:FVC ratio. Decreased DLCO is not specific for ILD, as it may also occur with pulmonary hypertension, which can occur in patients with a variety of connective tissue diseases. Chest radiographs may have changes suggestive of ILD, but HRCT of the lungs is considered the standard procedure for initial evaluation of patients with suspected ILD. The most common pattern observed in adult DM is irregular linear opacities with areas of consolidation and ground-glass attenuation, suggesting active inflammation.[115] Honeycombing occurs uncommonly. The differential diagnosis for ILD always includes infection and drug-induced lung disease. BAL can help rule out infection. Although lung biopsies are not routinely performed in adult DM, in children where ILD is uncommon and there are no data on the role of HCRT in predicting histological patterns, a lung biopsy may be required to obtain a diagnosis. Pulmonary fibrosis,[120] acute interstitial pneumonitis,[119] BOOP[105] (see Fig. 58.4), and DAD[122] have all been reported as lung histological findings in JDM.

Many observational studies have reported asymptomatic pulmonary function abnormalities in 30%–40% of children with JDM,[105] A small longitudinal case series reported pulmonary function abnormalities in 5 of 12 patients with JDM who had no respiratory symptoms, but these abnormalities were generally of a mild nature and nonprogressive, showing a restrictive defect.[124] More recently, a larger case-control study of 59 JDM patients from Oslo showed a restrictive ventilatory defect in 26% compared with 9% of controls.[125] These mild nonprogressive restrictive pulmonary defects have generally been attributed to respiratory muscle weakness or calcinosis in the chest wall and need to be differentiated from the reduced lung compliance that occurs with ILD. Findings of reduced maximal inspiratory and expiratory pressures, reduced maximal voluntary ventilation, normal DLCO, and increased residual volume without decreased $FEV_1$:FVC ratio help distinguish respiratory muscle weakness from ILD.

## Treatment

The mainstay of treatment is high-dose corticosteroids, usually weaned slowly over a 1–2 years period. Intravenous pulse methylprednisolone is frequently used for children with more severe weakness. Immunosuppressive therapy is used to treat JDM, based mainly upon results reported in observational studies and clinical experience.[126] In a single randomized but unblended multicenter trial, 139 children with new-onset JDM were assigned to prednisone alone, prednisone plus methotrexate, or prednisone plus cyclosporine: the two combination arms had better efficacy but more adverse events, particularly infection, compared with prednisone alone.[127] The most commonly used immunosuppressive agent is methotrexate administered weekly. Since reports of the benefits of methotrexate in reducing the duration and cumulative dose of systemic corticosteroids have emerged, in many centers, methotrexate is routinely added to systemic steroids at the initiation of treatment.[128] There are also reports of the efficacy and steroid sparing effects of cyclosporine in JDM,[129] and some clinicians use cyclosporine as initial therapy together with prednisone.[130] Cyclosporine has also been reported to be effective in combination with systemic corticosteroids in the treatment of a small series of children with JDM-associated ILD.[131] Controlled trials of intravenous immunoglobulin in adults,[132] and uncontrolled trials in children, support its use.[133] In patients with severe or life-threatening disease, such as ILD, chronic skin ulceration, or gastrointestinal involvement, intravenous CYC (500–750 mg/m$^2$ every 4 weeks) is used in combination with high-dose corticosteroid therapy.[134] Rituximab has been shown to be associated with clinical improvement in two small case series of severe JDM[135,136] and a randomized trial that included 48 children with refractory JDM.[137] Case reports have also suggested improvement in selected refractory JDM patients with infliximab[138] and abatacept.[139]

## Prognosis

Mortality rates for JDM declined from more than 30% in the 1960s before routine glucocorticoid therapy was given, to less than 3% in the 2000s with the advent of early combination immunosuppressive therapy.[126] Patients with typical disease who are treated with early immunosuppressive therapy now usually have an excellent prognosis.[140] Long-term morbidity is generally related to disease complications, such as calcinosis and other complications related to drug toxicity, including growth retardation and osteoporosis.[141] Acute onset and rapidly progressive ILD with associated air leak is only very occasionally a cause of mortality in JDM.[119–121] Small defects in pulmonary function should be followed over time to ensure that slowly progressive ILD, which is well described in adult DM, does not develop.

# Scleroderma

## Epidemiology

Systemic scleroderma, also known as systemic sclerosis (SSc), is a connective tissue disease marked by typical skin thickening and hardening (sclerosis) and multiorgan fibrotic changes. It is rare in childhood. One study of Finnish children found an incidence of juvenile SSc of 0.05 per 100,000,[142] while a 2005–2007 survey in the UK and Ireland found an incidence of 0.27 cases per million children.[143] It has been estimated that up to 10% of adults with SSc have the onset of their disease in childhood.[144] In a large series of children from multiple countries, juvenile SSc was almost four times more common in females and began at a mean age of 8 years.[145]

## Clinical Features

SSc usually has an insidious onset in children with skin changes in the hands and face and/or Raynaud phenomenon. Other common presenting findings are constitutional symptoms (fatigue, weight loss), arthralgia, muscle weakness and pain, subcutaneous calcifications, dysphagia, and dyspnea. The time interval between onset of symptoms and diagnosis is often prolonged (average 1.9 years).

The skin abnormalities are often heralded by a phase of edema, which is then followed by the development of skin tightening and sclerosis, and as this becomes more prominent, contractures develop. When sclerosis affects the face, loss of wrinkling of the skin results in the pathognomonic expressionless facies. The skin can subsequently atrophy and develop telangiectasia. The vasculopathy is reflected in abnormalities easily seen in the nail fold capillaries with dropout, dilatation, tortuosity, and hemorrhages. Digital ulcers (with resulting digital pitting scars) accompanying Raynaud phenomena is very suggestive of SSc. The most common, nondermatologic clinical features of juvenile SSc in the two largest series reported to date[145,146] were Raynaud phenomenon (72%–84%), followed by musculoskeletal (arthralgias, muscle weakness and pain 64%–79%), gastrointestinal (esophageal dysfunction 65%–69%), and pulmonary (42%–50%) involvement. Cardiovascular (29%–44%), renal (10%–13%), and neurologic disease (3%–16%) occurred less frequently. Calcinosis developed in 18%–27%. The disease tends to be most active during the first 5 years after onset, when skin sclerosis advances rapidly and visceral involvement commonly occurs. After 5 years, constitutional symptoms abate, skin abnormalities often stabilize or even improve, but visceral disease may progress.

Systemic sclerosis can be divided into limited and diffuse forms. Skin involvement is limited to an acral distribution (hands, face, and feet) with limited disease, while diffuse disease has truncal and acral skin involvement and usually early and significant multiorgan disease. More than 90% of children with juvenile SSc have the diffuse form.[145] A higher proportion of children than adults with the disease have features of an overlap connective tissue disease syndrome.[147]

SSc is classified according to the extent of skin and pattern of internal organ involvement. Consensus-based classification criteria for juvenile SSc have been proposed for children whose disease begins before the age of 16 years.[148] These criteria require the presence of the major criterion of proximal sclerodermatous changes and at least two of the minor criteria, which have been expanded to 20 items, including involvement of other organ systems as well as some serological abnormalities (ANA and systemic sclerosis selective autoantibodies).[148] The minor criteria are sclerodactyly, peripheral vascular disease (Raynaud phenomenon, nail fold capillary abnormalities, digital tip ulcers), gastrointestinal (dysphagia, reflux), cardiac (arrhythmia, heart failure), renal (renal crisis, hypertension), neurologic (neuropathy, carpal tunnel syndrome) and musculoskeletal disease (tendon friction rub, arthritis, myositis), respiratory (DLCO of <80% predicted), PAH, and pulmonary fibrosis seen on chest radiography or HRCT and serology (antinuclear antibodies, SSc selective autoantibodies [anticentromere, antitopoisomerase I [Scl-70], antifibrillarin, anti-PM/Scl, antifibrillin, or anti-RNA polymerase I or III]). The 1980 criteria for adult SSc[149] have been widely used for children in the past. These rely on either the presence of the major criterion of sclerodermatous changes proximal to the metacarpophalangeal or metatarsophalangeal joints or the presence of at least two of the following minor criteria: sclerodactyly, digital pitting scars, or bibasilar pulmonary fibrosis.

## Pathogenesis

SSc is characterized by inflammation, excessive fibrosis and vasculopathy affecting the skin, and multiple organs with evidence of immune, endothelial, and fibroblast dysfunction. While the etiology and exact pathogenetic mechanisms remain elusive, endothelial cell injury appears to be an early and important event. Endothelin-1 has emerged as an important mediator of the vascular changes, and serum levels correlate with disease severity markers.[150] There are features of autoimmunity with the following SSc-selective autoantibodies included in the new proposed minor criteria: anticentromere, antitopoisomerase I (Scl-70), antifibrillarin, anti-PM-Scl, antifibrillin, and anti-RNA polymerase I or III. ANA is found in approximately 80%, ENA in 40%, and anti-Scl-70 in approximately one-third of pediatric patients.[145]

## Pulmonary Involvement

ILD (Figs. 58.7 and 58.8), PAH, and cardiomyopathy are dreaded organ manifestations associated with mortality in children; initial workup and monitoring should focus on detecting these manifestations. ILD, while relatively common in adults, is rare in children. Hence, most of what we know about the characteristics and risk factors for ILD, prognosis and treatment comes from adult studies. ILD is best detected on HRCT.[151] Dyspnea and dry cough are late symptoms. Pulmonary function tests (FVC and DLCO) correlate with severity of disease. The typical form of ILD (seen in 77.5% of adult cases) has a histological pattern of NSIP, while a few cases have a UIP pattern.[152] When ILD occurs, it usually is detected at initial presentation or within the first 3 years after onset of symptoms. Not all cases of ILD progress; hence decisions on which cases to treat can be difficult.[153]

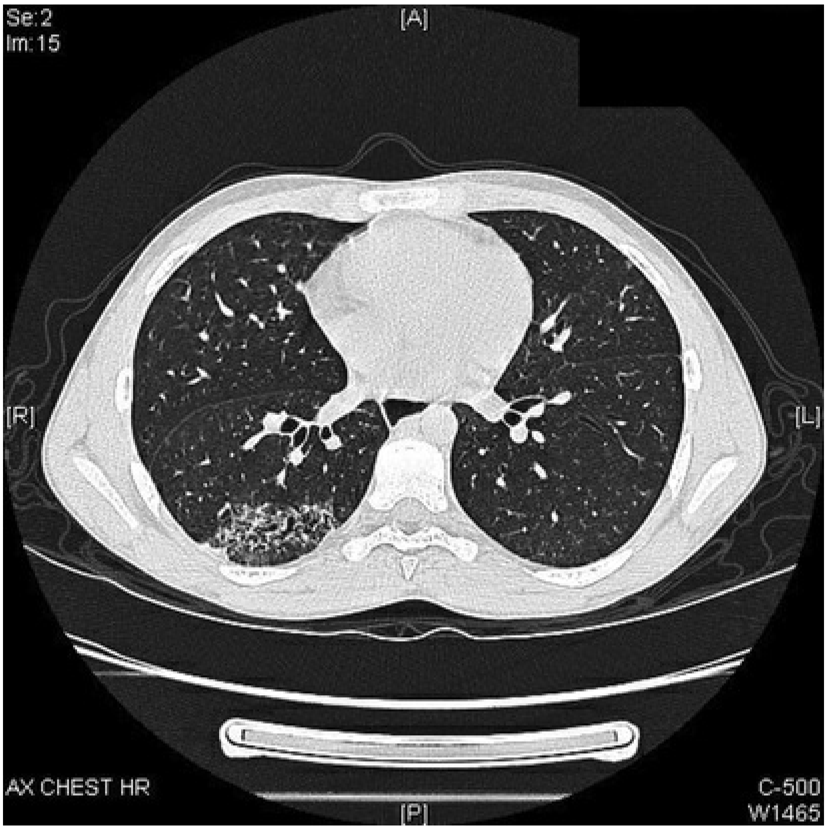

**FIG. 58.7** Early interstitial lung disease in teen with scleroderma. High-resolution computed tomography shows typical changes of peripheral interlobular septal thickening with fibrosis and traction bronchiectasis.

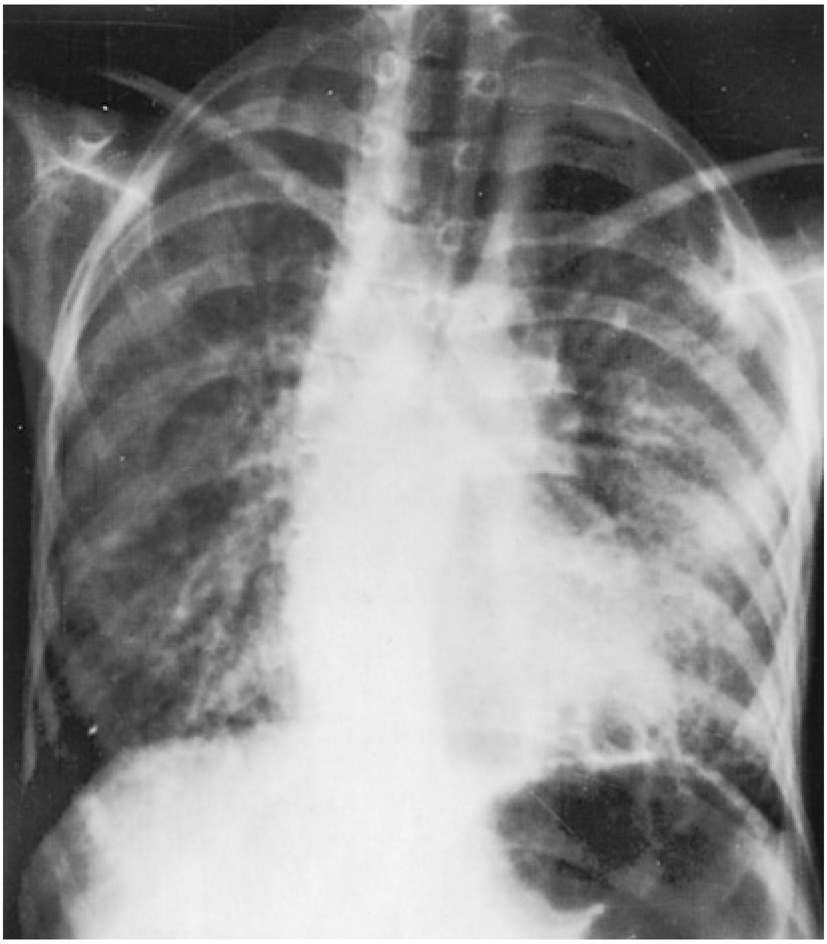

**FIG. 58.8** 18-year-old female who was diagnosed with scleroderma at 6 years of age and had onset of interstitial lung disease at age 10 years. This chest radiograph shows an advanced case of scleroderma lung with chronic pulmonary fibrosis in a reticulated honeycomb pattern more prominent in the lower lobes. The heart is minimally enlarged, gaseous distention of the proximal and distal thirds of the esophagus is present, and there is a moderate right convex scoliosis.

SSc is also associated with pleuritis, pleural effusions, bronchiectasis, BOOP, and alveolar hemorrhage. Spontaneous pneumothorax with severe fibrosis and aspiration pneumonia associated with esophageal reflux may also be seen.[153] ILD and progressive decline of pulmonary function have been associated with more severe esophageal dysmotility in adults with SSc.[154]

Pulmonary involvement is often asymptomatic. Although dyspnea is the most frequent symptom in children with lung involvement, it only occurs in 10%–26% of children with SSc at presentation or during the disease course.[155] Dry cough is even less frequent. Abnormal chest radiography is seen at presentation in 12% and in 29% during the disease course.[145] Ground-glass opacities are suggestive of ILD, and a reticular pattern and traction bronchiectasis may be seen.[153] High-resolution CT is a more sensitive method of detecting these findings and may find additional abnormalities in addition to ground glass densities, such as subpleural micronodules, linear opacities, and honeycombing appearance.[156,157] Patients with normal HRCT scans on initial assessment are likely to have normal HRCT scans after a follow-up period of 5 years.[158] One study in adults with SSc found that ground-glass opacity was the most common finding on HRCT and was only reversible in a small minority of patients who had sequential scans,[159] suggesting that ground-glass opacity may actually indicate fine fibrosis.

Global disease activity is monitored with a multidimensional disease severity score, the Juvenile Systemic Sclerosis Severity Score (J4S),[160] which includes measures of spirometry, DLCO, HRCT, and oxygen dependency. PFTs are important in the initial assessment and ongoing monitoring of patients with SSc. Reduced DLCO may be an early marker of ILD or PAH and also correlates with the severity of these disease manifestations.[153] Children with SSc most often have reduced forced vital capacity with a restrictive PFT pattern (42%–65%). It is important to note that almost half of those with abnormal PFTs do not have lung imaging abnormalities, calling into question the etiology of the decrements in lung function.[155] It is this author's opinion that some of these unexplained PFT decrements are due to limited chest wall expansion due to sclerodermatous changes of the thorax. Serial PFTs in adults with SSc and severe pulmonary fibrosis demonstrate that most of the lung volume loss occurs in the first 4 years of the disease.[161]

The best way to monitor pediatric SSc patients for the new onset of ILD or progression of ILD is not clear. A study of serial PFTs and HRCT in children with SSc found that PFTs, particularly lung volume studies, correlate with findings on HRCT, suggesting that monitoring with PFTs can identify which patients require follow-up HRCT. The authors acknowledge, however, that PFTs do not completely exclude mild pulmonary involvement, and they therefore entertain the notion of a surveillance low-radiation dose HRCT at some point during follow-up for lung disease.[162] More extensive disease on HRCT correlates with poor prognosis in adult SSc patients.[163]

In adults, anti-Scl-70 antibodies are associated with ILD, while anticentromere antibodies are protective.[164] In children, serum KL-6 has been reported as a potentially useful biomarker of ILD in juvenile SSc and correlates with PFT abnormalities and the severity of ILD.[165] Lung biopsy is generally not required when the clinical features, pulmonary function test results, and imaging findings are typical for ILD. Moreover, pathological findings do not reliably predict disease course and outcome.[152] BAL has not been found to predict disease course reliably or response to treatment.[166]

PAH may occur as an isolated phenomenon or in association with ILD. Right heart catheterization may be the gold standard for identifying PAH, but Doppler echocardiography is effective and noninvasive. Anticentromere antibodies are associated with isolated PAH, and anti-U3 RNP antibodies are associated with PAH in adults with SSc.[167]

## Treatment

Nonpharmacologic therapy measures include skin care, exercise programs, and corrective splints as needed. Pharmacologic therapy tends to be targeted toward controlling disease in specifically involved organs. There have been no controlled treatment trials in juvenile SSc. Treatment approaches for juvenile SSc–related lung disease have therefore drawn heavily on reports of successful treatment in adults. Both daily oral CYC[168] and monthly intravenous CYC[169] have demonstrated some degree of efficacy in ILD associated with SSc, with only modest benefits on respiratory function. There are only uncontrolled studies using mycophenolate mofetil, azathioprine, and rituximab in adults. Lung transplantation has been successful in carefully selected patients who have limited involvement of other major organs.[170] Autologous hematopoietic stem cell transplantation has also been shown to stabilize major organ disease and is currently being evaluated in controlled trials.[171]

## Prognosis

Prognosis is generally better in childhood-onset compared with adult-onset SSc, likely due to lower rates of ILD and PAH. Survival rates of juvenile SSc at 5, 10, 15, and 20 years after diagnosis are 89%, 80%–87%, 74%–87%, and 69%–82%, respectively.[146,147,172] The mortality risk in adults with SSc is dramatically higher with PAH, and survival is negatively impacted by lung disease, even without PAH.[173] Survival in pulmonary hypertension associated with ILD is significantly worse than isolated PAH.[174] Similarly, in children with a fatal outcome, pulmonary involvement occurs more frequently and earlier in the disease course. Antitopoisomerase I (anti-Scl-70) antibodies and anti-U3RNP antibodies are associated with pulmonary fibrosis and poor prognosis in adults, but not children.[172,175] However, some children with early organ involvement have a rapidly progressive course. Scleroderma-related heart disease is a frequent cause of death among children with SSc.[147] In adults, some risk factors for mortality and progression of SSc associated ILD have been identified, including older age, lower FVC, lower diffusing capacity for carbon monoxide, and extent of disease on HRCT chest imaging.[176] Similar work has not been done in childhood onset SSc and is more difficult due to the rarity of ILD in children. However, one should cautiously and carefully monitor children with ILD, as some do follow a rapidly progressive course.

# Mixed Connective Tissue Disease

MCTD is a very rare diagnosis in children but can have life-threatening pulmonary involvement. It is characterized by the presence of high titer anti-U1 ribonucleoprotein (RNP) antibodies in combination with clinical features of SLE, SSc, or DM and was first described as a distinct clinical phenotype in 1972.[177]

## Epidemiology and Pathogenesis

MCTD accounts for only 0.1%–0.5% of pediatric rheumatology cases.[178] Median age of childhood onset is approximately 11 years

(4–16 years) with girls diagnosed three times more often than boys.[178] More commonly MCTD presents in women in the second to third decade of life, although pediatric onset accounts for 25% of cases.[179]

The etiology of MCTD is unknown. Complex interactions occur between the innate and adaptive immune system, and there is evidence that anti-RNP antibodies are involved in pathogenesis of disease.[180]

## Clinical Manifestations and Diagnosis

Children usually have an insidious onset of disease, with Raynaud phenomenon, constitutional symptoms (malaise, fatigue, and low-grade fever) and polyarthritis as initial clinical symptoms in combination with a high titer of speckled ANA pattern.[181–184] A high titer of anti-RNP antibodies is a strong predictor of the eventual evolution to MCTD.[185] Classic clinical manifestations of other connective tissue diseases (often the skin rash of SLE or JDM, SSc skin, swollen hands, proximal muscle weakness, esophageal dysmotility, pericarditis, leukopenia, and pulmonary dysfunction) develop sequentially over time but not in any predictable manner or time frame. A clear diagnosis of MCTD may not be evident for years, and the initial presenting syndrome may be referred to as "undifferentiated CTD."

Several sets of diagnostic criteria for MCTD exist; however, Kasukawa's criteria are used most frequently in children and are the most restrictive.[186] Three criteria must be fulfilled for diagnosis of MCTD: (1) Raynaud phenomenon or swollen fingers or hands, (2) anti-RNP antibody positive, and (3) at least one abnormal sign or symptom from two or more of these categories: SLE, SSc, or DM. Almost any organ can be involved in MCTD; however, there are four clinical features that are distinctive for MCTD: (1) the presence of Raynaud phenomenon and swollen hands or fingers, (2) the absence of severe renal or central nervous system disease (differentiates MCTD from SLE), (3) more severe arthritis with insidious onset of pulmonary hypertension (without pulmonary fibrosis), and (4) autoantibodies with specificity to anti-U1 RNP.

## Pulmonary Involvement

Pulmonary disease is a major source of morbidity and mortality in adults with MCTD, occurring in about 75% of adult patients.[187] Case series of MCTD in children suggest a similar frequency of pulmonary involvement, although pulmonary hypertension seems to be less common and lung disease is generally mild.[184] Pulmonary disease onset is often initially asymptomatic and develops insidiously. Common symptoms include dry cough, dyspnea with exertion, and chest pain. Pulmonary fibrosis, pleural effusions, and PAH are the most common manifestations. Other findings include thromboembolic disease, pulmonary hemorrhage, diaphragmatic dysfunction, and aspiration pneumonitis.[188]

PAH is due to a pulmonary vasculopathy with intimal proliferation and medial hypertrophy of pulmonary arterioles. Unlike SSc, the lung parenchyma is not fibrotic.[179] Although PAH is rare in children with MCTD, it can develop rapidly.[189] One adult case of pulmonary hypertension due to veno-occlusive disease has been reported.[190] PAH should be suspected, with symptoms of exertional dyspnea, increased second heart sound, dilatation of pulmonary arteries on chest imaging, or reduced DLCO on pulmonary function testing.

## Treatment
